was exposed to an external field in which the observed magnetisation was acquired³, and Urey and Runcorn⁴ and Strangway and Sharpe⁵ have conjectured that the Moon was magnetised, more or less homogeneously, early in its history, and that the present magnetisation was acquired in this remanent field. The primitive remanent field was later thermally demagnetised as the Moon heated up internally. Finally, there are models in which local and transient fields are invoked. These models tend to merge into zero-field or 'bootstrap' models which require fields no larger than the present field associated with the solar wind. Here I present another possibility, which is a variant of the remanent field models already proposed.

I suggest that the Moon acquired a primitive magnetisation during its formation by accretion from planetesimals. Two mechanisms of magnetisation are likely to have been predominantly important. First, thermoremanent magnetisation would be acquired by material which was heated above its Curie point during impacts and subsequently cooled. Second, shock magnetisation would be acquired by material which was shocked but not heated significantly by the impacts⁶.

The nature of the fields in which the proposed magnetisation was acquired remains obscure. At an early stage of the Solar System an enhanced solar wind field is not, however, implausible. Also, because the mechanisms of thermoremanent and shock magnetisation are efficient, it is not necessary to propose as large a field as in the isothermal remanence model⁵. Finally, if these ideas are combined with those of A. E. Ringwood's recent models of the origin of the Moon (unpublished), it seems possible to invoke an early geomagnetic field as a source field for the primitive magnetisation of the Moon. In this view, the Moon accretes from a ring of planetesimals in a near-Earth orbit, so that if this process took place after the formation of the Earth's core, as seems likely, the terrestrial dynamo may already have been generating a geomagnetic field.

Whether an impact, or an external field origin is invoked, the primitive magnetisation of the Moon is likely to have been inhomogeneous. Its magnitude and direction would have been controlled by the geometries of impacts and of ambient fields. The latter would change with the proto-Moon's position in its orbit. In this respect, my suggestion differs from earlier models⁶ in that they propose a more or less homogeneously magnetised Moon. My explanation derives in part from an earlier suggestion made by Meadows⁷ to account for the magnetism of meteorites.

The chief difficulty with the remanent field approach lies in explaining any very strong NRM carried by the returned samples, which would imply inducing fields of the order of 1 oersted. It is not yet clear whether a significant fraction of the returned samples carry such NRM, so this may not be a critical difficulty. Nevertheless, if large numbers of samples do turn out to imply such strong inducing fields, the present suggestion will be seriously weakened. It will then be necessary to invoke somewhat *ad hoc* field amplification mechanisms to account for the high fields, compared with the fields of about $10^3\gamma$ which remanent field models seem capable of giving at the surface.

My suggestion follows the earlier remanent field models^{4,5} in the explanation of the loss of the primitive magnetisation by later internal heating of the Moon. The field could, however, be maintained by an early cool Moon at least long enough for the crust of the Moon to be magnetised when it was formed. This magnetisation of the crust would have been primarily a thermoremanent magnetisation (TRM), but shock magnetisation is also likely to have been involved since impacts took place while the field was present. A critical prediction is that the primitive magnetisation of the Moon was inhomogeneous on a Moon-wide scale, so that the magnetisation of the crust would also be inhomogeneous on the same scale. It certainly could, however, be homogeneous over scale lengths of hundreds of kilometres. This prediction can probably be tested by the magnetometer experiment on the Lunar Polar Orbiter.

If magnetisation by the process suggested here is important in the Moon, then it should also be so in other bodies of the

Solar System which were formed in the presence of magnetic fields. If the body remained cool, a record of the process should be preserved. If the body subsequently heated up internally, the magnetisation should have been lost and the surface record of the primitive magnetisation progressively obscured by later impacts and other effects. These may take place in very weak fields and thus demagnetise material, or in later dynamo fields, in which case new patterns of magnetisation will be generated.

Recent crustal movements along Mediterranean coastal plain of Israel

THE high density of population along the Mediterranean coast of Israel dictates caution in the siting of power stations and major engineering structures. One of the critical questions is whether the coastal plain of Israel may be assumed to be tectonically quiet and stable. Lately¹, evidence was presented of Recent (probably later than 700 BP and certainly not earlier than 3,700 BP) faulting along the coast, and the coastline was assumed to be tectonic in origin, in contrast to the previously held notions of tectonic calm and a coastline shaped by wave abrasion^{2,3}. Though unable at this stage to comment on the regional implications of this controversy, we report that repeated precise levelling suggests the present occurrence of differential crustal movements along the coastal plain and the nearby Judea mountains.

Our data, based on 251 twice-levelled benchmarks aligned in seven complete and three incomplete polygons (Fig. 1), include the computed differences, between differences in elevation between consecutive benchmarks, determined in the 1962 and 1969 circuits in levelling ($dH = \Delta H_{1962} - \Delta H_{1969}$). Monumentation and geodetic operations conformed to specifications of first order precise levelling^{4,5}, discrepancy between the forward and backward measurement not exceeding $3\sqrt{D}$ mm (D is the levelled distance in km). The dH values are not related in sign nor magnitude to the discrepancies, and in most cases are significantly larger.

Figure 1 shows the locations of the studied benchmarks and the range of the computed dH values. Tide data are lacking and thus the dH values can not be related to the mean sea level. Instead, they are presented relative to a reference benchmark, with respect to which all other benchmarks subside (zero point in Fig. 1). The numbers shown on the map indicate in mm the lower and upper limits of the 1962–69 relative subsidence for each closed polygon. Arrows show the direction of tilt, and crosses indicate even subsidence relative to the reference benchmark.

Figure 1 indicates a pronounced regional tilt to the south-east and east-south-east. The differences between the adjacent polygons vaguely suggest a possible block-structure, related to the E–W trending normal faults revealed in gravity surveys of the coastal plain^{6,7}. Rate of movement and rate of tilting increase southwards. Polygons I, II, and III show a relatively gentle movement, the northernmost one subsiding evenly and

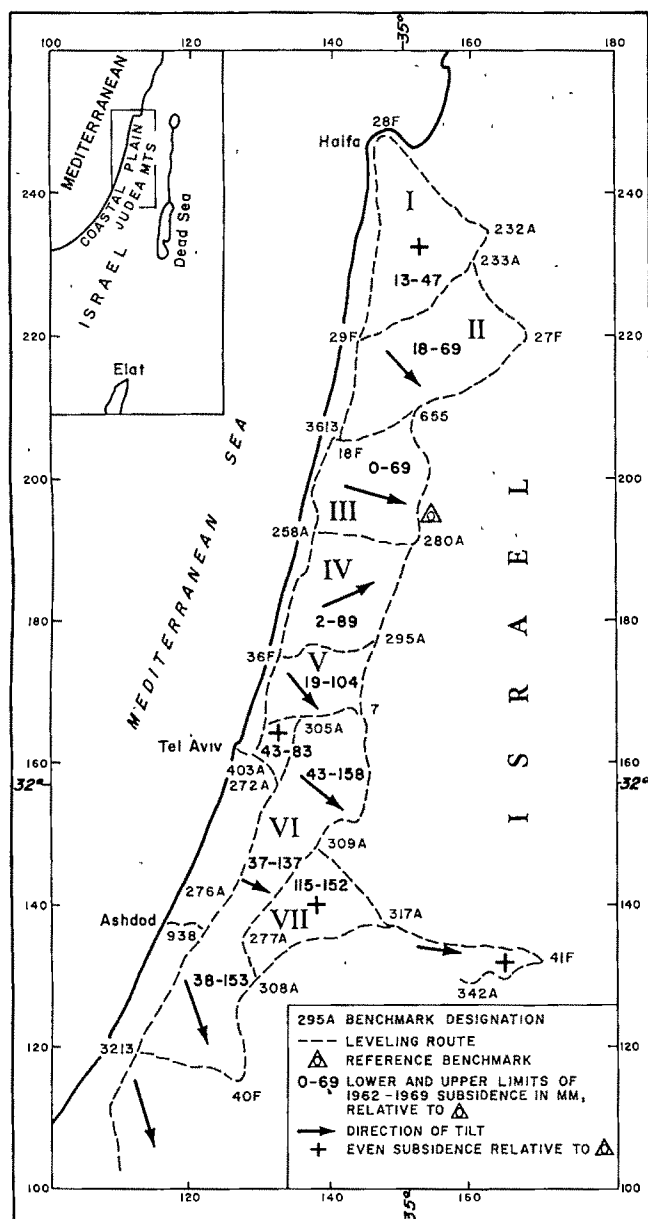

Fig. 1 Area of survey, showing variations in tilt.

the other two tilted towards ESE and SE. In polygons V and VI, tilts are stronger and the dH values reach 150 mm (an inferred movement of about 2 cm yr^{-1}). The strong easterly component of tilt suggests that the Judea mountains anticlinorium subsides relative to the coastal plain. This tendency of structural highs to sink, and of structural lows to rise, was reported also from other parts of the region⁸ and was tentatively attributed to gravity-compensation effects. It is not clear whether the southerly increase in rate of movement and tilt is tectonically controlled, or is caused by another factor such as differential loading due to a southerly increase in thickness of the sediments derived from the Nile^{9,10}.

Geological structure of the coastal plain is unexposed and structural details must be inferred from geophysical surveys and borehole correlations, thus disallowing a more detailed evaluation of the possible relationship between the dH movement of individual benchmarks and their structural setting.

The magnitude of inferred vertical crustal movements reported here is very considerable and must await verification by further levelling especially as only 25% of the benchmarks are anchored in bedrock. The time interval between the studied levellings is too short to reveal whether the dH values reflect a

consistent long term trend, or whether they are but a part of short term oscillations. But geological evidence of young tectonic activity in Israel reported in the past, and confirmed by seismological data^{11,12} indicates that the possibility of significant present day strain accumulation cannot be ignored.

Influence of mantle CO_2 in the generation of carbonatites and kimberlites

THE explanation of why partial fusion of mantle peridotite sometimes yields basalts, sometimes kimberlites and sometimes carbonatites is given by the phase relationships in the system $\text{CaO-MgO-SiO}_2\text{-CO}_2$. The key is the intersection of a sub-solidus carbonation reaction with the solidus, which introduces carbonates as primary minerals alongside silicates on the surface of the liquidus.

The mineral assemblage forsterite (Fo) + orthopyroxene (Opx) + clinopyroxene (Cpx) in the system CaO-MgO-SiO_2 has been used by Kushiro¹ as a model for mantle peridotite, both dry and in the presence of H_2O , and by Eggler² in the presence of CO_2 . The P - T diagram of Fig. 1 compares the solidus curve for the mineral assemblage free from volatiles with the melting curves produced by solution of H_2O or CO_2 . At 20 kbar, the melting temperature is lowered through more than 400°C by the solution of about 20 weight % H_2O , and through 75°C by the solution of about 5 weight % CO_2 . The model mantle peridotite yields a haplobasaltic liquid that is forsterite-normative. In the presence of H_2O the liquid is enriched in SiO_2 and it is quartz-normative at 20 kbar (ref. 1). In the presence of CO_2 the liquid is depleted in SiO_2 , and somewhere between 15 and 30 kbar it becomes larnite-normative³, a haplokimberlite magma.

Our new data between 25 and 35 kbar show the solidus in the presence of CO_2 sweeping down through 400°C through a pressure maximum at about 32 kbar, and terminating at invariant point Q_6 near 25 kbar and $1,200^\circ\text{C}$. This is the point where the subsolidus carbonation reaction for the mantle mineral assemblage (Fig. 2) terminates by addition of a liquid phase. Increase in pressure not only stabilises carbonate in the subsolidus mineral assemblage, but also in the liquid phase; this produces a large increase in CO_2 solubility and a dramatic change in melting temperature.

Figure 2 is an isobaric isothermal diagram showing the compositions of the minerals involved in the subsolidus carbonation reaction at mantle pressures, with dots giving the compositions of pyroxenes and carbonates coexisting across solvi⁴⁻⁶. On the high pressure side of the reaction, the assemblage Fo + Opx + Cpx reacts to produce Cd (solid solution between calcite and dolomite) at the expense of Cpx. This reaction was reported in an

Fig. 1 The melting curve for mantle peridotite assemblage forsterite (Fo) + orthopyroxene (Opx) + clinopyroxene (Cpx), compared with reactions in the presence of H_2O , and with a small proportion of CO_2 , either as vapour phase at lower pressures, or as crystalline carbonate at higher pressures. Cd or Ccd = Solid solution between calcite and dolomite; L = liquid; Ph = phlogopite; En = enstatite. Of particular interest is the dramatic change in CO_2 -melting reactions between 25 and 35 kbar. (The numbering system, Q_6 , Q_{11a} , refers to a detailed account of the whole system, now in preparation.)

abstract by Eggler, but with a magnesian carbonate⁶. The solidus curve rising to higher pressures from Q_6 involves silicates and the carbonate. The first liquid produced is a haplo-carbonatite with about 90% by weight of carbonate.

Figure 3 shows the CO_2 -saturated liquidus surface in CaO - MgO - SiO_2 - CO_2 at 28 kbar (refs 5-8 and our unpublished work). For silicates in the area SiO_2 - $CaSiO_3$ - $MgSiO_3$, CO_2 solubility remains low, but for compositions ranging from the pyroxene join to the carbonate join, the CO_2 content of liquids increases significantly. Note the position of the field boundary between the silicates and the carbonate solid solutions, and the liquidus minimum at point m on this surface. This minimum (and related reactions at other pressures) is represented in Fig. 1 by the dashed line solidus at temperature slightly below Q_6 . This is close to the melting curve for phlogopite coexisting with mantle minerals and H_2O (ref. 9). Figure 1 shows the range of existence for haplo-carbonatites with compositions in the general area

Fig. 2 Isobaric isothermal diagram showing mineral compositions in the univariant carbonation reaction for the mantle mineral assemblage. This is the reaction terminating at invariant point Q_6 in Fig. 1, with the addition of a liquid phase. All phase assemblages shown coexist with CO_2 (V = vapour).

between m and a in Fig. 3. The solidus reaction without CO_2 rising to higher pressures from Q_6 would be represented in Fig. 3 by a point behind the liquidus surface, somewhat further away from the CO_2 apex than liquids m and a , but with similar high contents of dissolved carbonates.

At 28 kbar (Fig. 1) the melting reaction for the assemblage $Fo + Opx + Cpx + CO_2$ is intersected twice, and the liquid compositions are represented in Fig. 3 by the higher temperature liquid b (haplokimberlite) and the lower temperature liquid a (haplo-carbonatite). With increasing pressure, points a and b approach each other, becoming coincident at about 32 kbar (Fig. 1). At greater pressures, the CO_2 -saturated liquidus fields for forsterite and clinopyroxenes are separated by the field for orthopyroxene.

The peridotite carbonation reaction in Figs 1 and 2 occurs at lower pressures than the forsterite carbonation reaction in the system MgO - SiO_2 - CO_2 as determined by Newton and Sharp¹⁰. According to the geotherms¹¹ and the reaction in Fig. 1, we confirm their conclusion that free CO_2 cannot exist in the upper mantle except in conditions of unusually high temperature. CO_2 exists in the upper mantle as carbonate^{10,12}. The reaction is displaced to lower temperatures in the presence of diluted

Fig. 3 CO_2 -saturated liquidus surface in CaO - MgO - SiO_2 - CO_2 at 28 kbar, partly schematic. The surface gives the compositions of liquids that can coexist with free CO_2 , and shows the fields for primary crystallisation of minerals. Cm, Cd, and Ccd are carbonate solid solutions; Qz = quartz; 2L = immiscible liquids. Note the continuous crystallisation or fusion paths between haplo-basalt (liquids in area olivine-pyroxenes), haplokimberlite, liquid b , and haplo-carbonatite, liquid a .

CO_2 , however, so CO_2 could exist within a restricted depth interval in a CO_2 - H_2O vapour phase, probably of limited compositional range.

The seismic low velocity zone may be caused by incipient melting due to the presence of traces of H_2O in the upper mantle^{13, 14}. Green concluded that melting was not involved, and that the low seismic velocities were caused by exsolution of CO_2 from dry silicate minerals^{15,16}. Figure 1, however, shows that mantle peridotite with CO_2 must begin to melt in the depth range 80-130 km.

In the presence of CO_2 , partial fusion of mantle peridotite at depths shallower than 80 km produces basaltic magmas, which become more undersaturated with silica at increasing depth². At depths greater than 80 km, the first magmas produced, in small quantities, are carbonatites. With progressive fusion these are converted to kimberlites and eventually, at higher temperatures, to basalts.

Any of these magmas, with fractional crystallisation at constant pressure, can yield carbonatite as residual magma at

considerably lower temperatures^{6,7}. Kimberlites or carbonatites rising from the low velocity zone must evolve CO₂ as they reach the reaction boundary at depths between about 100 and 80 km. This would certainly contribute to the explosive emplacement of kimberlites.

Palaeogeothermal gradients derived from xenoliths in kimberlite

GREAT problems exist in the determination of an ancient geothermal gradient. An attempt has been made by Boyd¹, based primarily upon the equilibration conditions of co-existing pyroxenes in garnet lherzolite xenoliths from the Thaba Putsoa, Letseng and Mothae kimberlite intrusions in northern Lesotho. He derived the equilibration temperature of the xenoliths from the amount of enstatite in solid solution in the diopside², and estimated the pressure from the amount of Al₂O₃ in the orthopyroxene³. He argued that, for a group of lherzolite xenoliths, a line joining a series of pyroxene-derived pressure/temperature points should define the geothermal gradient in the mantle below northern Lesotho during the Cretaceous when the xenoliths were entrained by the kimberlite during its ascent. He found a Cretaceous gradient similar to that in present-day shield areas between depths of 100 and 150 km, though from 150 to 200 km depth it was considerably steeper. Moreover, whereas the lherzolites outlining the shallower 'normal' part of the gradient are of granular texture, those outlining the high-temperature, steeper and deeper segment exhibit a range of deformation and recrystallisation textures (the porphyroclastic and mosaic textures in the classification scheme of Bouillier and Nicolas⁴).

Accordingly, it has been proposed^{1,5} that the perturbation of the normal subcratonic gradient was caused by stress heating at the base of the African Plate during the breakup of Gondwanaland in the Cretaceous, with the 150 km inflection point on the gradient being the top of the sheared, low-velocity zone at that time. Inflected geothermal gradients have been proposed within the upper mantle beneath other parts of the South African Shield, the North American Craton and the Siberian Shield, based on granular and deformed peridotite suites from Jagersfontein⁶; Louwrencia⁷, SW Africa; Black Butte diatreme, Montana⁸; Ming Bar diatreme, Wyoming⁹; and the Udachnaya diatreme, Yakutia¹⁰. These data cannot, however, be accepted unreservedly as

typical of events within the upper mantle at the time of the generation and ascent of the kimberlite magma. There is evidence to the contrary in xenolith suites from at least three different kimberlite intrusions.

The peridotites and pyroxenites from the Matsoku kimberlite diatreme, Lesotho, have been more thoroughly investigated than any other xenolith suite¹¹⁻¹³. They show a wide variety of textures, including those falling into the 'sheared' class of Nixon and Boyd⁸. But no matter what degree of deformation the Matsoku xenoliths have undergone, they all apparently equilibrated under the same pressure/temperature (PT) conditions and there is thus no correlation between deformation and increased temperature of equilibration in this particular xenolith suite. The restricted PT conditions indicated are those of Boyd's¹ coarse granular suite. As the Matsoku kimberlite is closely contemporaneous with the Thaba Putsoa kimberlite, and is only 20 km from it, it is difficult to accept a hypothesis involving large-scale horizontal movements in the upper mantle that did not have similar effects at both localities.

In the case of the xenolith suite from the Frank Smith Mine, north of Kimberley, a variety of deformation textures can be found in rocks apparently derived from a restricted mantle zone¹⁴, although the range does not include granular textures as it does at Matsoku, and the equilibration temperatures are close to 1,250 °C.

We have been investigating a suite of xenoliths from the Bultfontein kimberlite diatreme, Kimberley. The garnet lherzolites show a greater textural range than those from Thaba Putsoa and we have recognised a new textural type that indicates a greater degree of deformation than recognised previously in kimberlite xenoliths. This new texture, which may be regarded as a more deformed extension of Bouillier and Nicolas' fluidal mosaic texture¹⁵, comprises recrystallised orthopyroxene neoblasts strung out into bands that alternate with bands of fine-grained olivine neoblasts; furthermore, garnet unaffected by lower degrees of deformation has been disrupted and strung out into chains of small crystals. We call this texture 'banded and disrupted' (BAD).

We have analysed the phases in 26 selected garnet lherzolites from Bultfontein, covering the range of textural types from granular to BAD. The data will be published elsewhere but Table 1 shows analyses of phases in typical

Fig. 1 Plot of Al₂O₃ (in orthopyroxene) against Ca/Ca + Mg (in clinopyroxene) for xenolith suites from Thaba Putsoa⁵ (open symbols) and Bultfontein (solid symbols). Triangles, minerals in rock of granular texture; circles, minerals in rocks of flaser (Bultfontein) and sheared (Thaba Putsoa) texture. The Bultfontein flaser peridotites exhibit porphyroclastic, mosaic and BAD textures.

rocks from the two ends of the deformation spectrum. For the suite as a whole there are three pertinent features. First, no matter what the texture, the Ca/Ca+Mg ratio of the clinopyroxene is in the range 0.422–0.484 (wt %), indicating equilibration temperatures of 950–1,050 °C (ref. 2). Second, the Al₂O₃ content of all the orthopyroxenes is very similar to that in lherzolite orthopyroxenes in the Matsoku kimberlite (0.73–0.89 wt %), again indicating equilibration over a restricted pressure (depth) interval (Fig. 1). In view of the absence of experimental data on orthopyroxenes containing less than 2 wt% Al₂O₃, we are not prepared to draw any pressure (depth) implications from our results, other than to submit that they are of mantle origin, within the garnet lherzolite stability field. Third, the composition of the garnets is broadly similar in most lherzolites, with the exception that in a very few of the more deformed lherzolites, there are small increases in the TiO₂ content.

These data provide evidence that increased deformation cannot always be correlated with significant increases in temperature of equilibration or with increased depth or origin, as is the case for Thaba Putsoa xenoliths. Further, we have observed deformation gradients from granular to BAD textures within the same hand specimens over a distance of 2–3 cm and must assume that the deformation may be both very localised and very variable. This is not consistent with a major tectonic boundary, and may be caused by variable hydrolitic weakening.

It is clear that within the xenolith suite from each locality there is evidence of major deformation, consistent with differential movements in the upper mantle. One feature that is not clear is the sense of these movements. Strong lateral movements, accompanying the breakup of Gondwanaland, are proposed in the Thaba Putsoa model of Nixon and Boyd⁴, whereas the model for the origin of kimberlites by diapiric upwelling in the upper mantle¹⁶, invokes strong vertical movements. The evidence of individuality in the range of textures and equilibration conditions of xenolith suites from different diatremes is possibly more consistent with the latter hypothesis in that it links the characteristics of a xenolith suite with the particular upper mantle movements that culminate in the

emplacement of the kimberlite intrusions. Nonetheless, we do not exclude the possibility that some of the textures developed during the kimberlite event may be additional to textures developed during earlier upper mantle creep. A model involving vertical movement finds support in the geological evidence in that, during the Cretaceous, when most South African kimberlites were emplaced, the South African continent was subjected to strong vertical movements, resulting in peripheral faults downthrowing 18,000 m towards the contiguous ocean basins¹⁷.

Morarian Orogeny and Grenville Belt in Britain

Now that the nature of the Morarian orogenesis (about 730 Myr BP) is becoming more apparent^{1,2} it seems appropriate to assess its significance in terms of late Proterozoic history of the northern Atlantic region. It has been argued³ that the event is related to subduction, with a suture partly coinciding with the Great Glen Fault. The event has also been associated with the closing of a Precambrian ocean during the time represented by the unconformity between the Stoer and Torridon groups⁴. The Proto-Atlantic opened after the deposition of the Torridon Group. In establishing the orogenic character of the Morarian Event several features are important. First, the event is known to have affected Moine rocks in a zone some 20 km wide. If, as seems likely, the Morarian fabric can be traced as far south as the Great Glen Fault then the belt is some 50 km wide after the Caledonian shortening. Until more is known about the geology of Sutherland, however, it is uncertain whether the entire length of the Moine outcrop (about 250 km) is involved. There is no reason to believe that the Morarian fabric is present to the south of the Great Glen Fault: the likelihood is that the Central Highland Granulites (often named the Moines nowadays) represent post-Moine sediments, but the possibility that they are Moines that were not influenced by the Morarian Orogeny cannot be excluded. Until this problem is resolved it would be prudent to revive the name Central Highlands Granulite for the sub-Dalradian rocks occurring to the south of the Great Glen Fault.

Second, the Morarian belt is an Alpine-type belt. At Glenelg, Lewisian basement has been tightly folded with the Moine cover. Comparable structures may be present in Sutherland where sheets (nappes) of Lewisian gneiss mark a continuation of the Sgurr Beag Slide⁵. In contrast to the Sgurr Beag Slide the tectonic features responsible for these sheets are marked by a substantial number of ultrabasic bodies (serpentines, scyellites, garnet-pyroxene rocks)⁶, which have penetrated the Lewisian and the surrounding Moines. These bodies are, therefore, synchronous with or later than the emplacement of the sheets. There is some evidence that the serpentines antedate the D2 deformation (Caledonian)⁷. It is conceivable that the Lewisian nappes in Sutherland belong to the Morarian Orogeny.

Third the Morarian Belt is asymmetrical. The vergence of the Morarian antiforms is eastwards⁸ in contrast to the westerly translation of the Caledonian structures in north-western Scotland. The 'root zone' of the Morarian antiforms is exposed in the Glenelg region where the western part of the zone has been truncated by the Moine Thrust. If the Lewisian sheets in Sutherland are Morarian nappes rooted to the west then the Moine Thrust in northern Scotland has cut off the root zone. The implication is that the root zone lies wholly or in part beneath the Moine Thrust.

Fourth, the Morarian Orogeny was associated with upper amphibolite facies metamorphism resulting in the development of migmatites on a regional scale. In spite of the apparent lack of igneous rock which can be related to the Morarian Event there are some grounds for regarding the Morarian as an orthotectonic belt.

Fifth, there is no obvious connection between the Morarian Orogeny and the Stoer and Torridon groups which seem to antedate it. Thus, neither of these groups can represent molasse and, setting aside the possibility that the Central Highland Granulites is such, there is no identifiable sedimentary deposit that can be linked with any uplift of the Morarian Orogen.

These considerations allow speculation about a plate-tectonic model in the context of the late Proterozoic history of the northern Atlantic region. Garson and Plant³ have inferred the presence of a subduction zone, active about 730 Myr BP, following the ultrabasic zone in Sutherland and along the line of the later Great Glen Fault. That hypothesis encounters, however, several difficulties⁷. The ultrabasic bodies are emplaced at a high level in the structural pile: they must have penetrated some 2–3 km of Moine rocks to reach their present position. Accordingly, I interpret them as high level diapirs, derived from oceanic lithosphere, which, of course, are not situated on a subduction zone. The geographical association of these bodies with Lewisian sheets is probably significant and suggests a tectonic control (a zone of sliding) for their emplacement. Another possible difficulty is that the model devised by Garson and Plant³ implies that the "Moine" and Dalradian rocks of the Grampian Highlands were deposited on oceanic crust situated to the south of the proposed subduction zone.

As an alternative hypothesis, I suggest that the Morarian suture is hidden beneath the Caledonian nappes, that is, the Glenelg and Rossshire nappes. This follows from the vergence of, and the westerly root for, the Morarian nappes. A further prospect is that the Morarian is a collision-type belt, and the implication of that (see ref. 8) would be that the Moines were deposited on one continent (the Baltic Shield or a microcontinent) and the Stoer and Torridon groups were deposited on another—the Laurentian.

If the portrayal of the Morarian as an orogenic event is correct then it is worth considering its setting in the wider context. On present evidence the event seems to have been localised: apart from in Spitzbergen⁹ and western Ireland¹⁰ there is no firm evidence from the northern Atlantic Region of orogenic activity at 800–700 Myr BP. It may be that the Morarian Event is commonly obscured, to an even greater degree than it is in Scotland, by strong Caledonian overprinting, and in this respect anomalous radiometric dates, such as the 700–800 Myr dates recorded in the Appalachians¹¹, are worth re-examination.

But assuming that the Morarian event was localised, the likely hypothesis is that it resulted from the closure of a small ocean basin before the episode of rifting that formed the later Proto-Atlantic⁴. Another possibility is that the Morarian Event represents a delayed closure of the Grenville Ocean in the region of Britain, thus forming the missing link in Britain between Canada and Scandinavia^{12,13}. Orogenic events took place at widely different times during the closure of the Proto-Atlantic and adjacent oceans, and incomplete suturing produced the Erian, Acadian and Taconic episodes⁴. Though the time span between the Grenville and the Morarian events is substantially greater than that separating the Taconic and Acadian episodes of the Caledonian Orogeny, it should be borne in mind that the dated Morarian pegmatites may only date the end of the Morarian Orogenic Cycle.

I thank Drs A. L. Harris and A. D. Stewart for their comments.

Magnetic properties of oceanic pillow basalts from Macquarie Island

We summarise here the results of a combined palaeomagnetic, hysteresis, thermomagnetic, and electron microprobe analysis of late Tertiary oceanic pillow basalts from Macquarie Island, which indicate that pillow basalts from a significant depth in the oceanic lithosphere have suffered burial metamorphism during the crustal accretion process. This metamorphism results in an intensity of natural remanent magnetisation (NRM) of $\sim 10^{-3}$ gauss, a substantial component of viscous remanent magnetisation (VRM), and an order of magnitude decrease in the Koenigsberger ratio relative to unaltered pillow basalts. Since a pillow lava layer with such a low NRM intensity is insufficient to account for the observed amplitude of marine magnetic anomalies, we conclude that in the case of Macquarie Island the underlying basaltic and doleritic dyke complex must also contribute to the observed anomalies.

Our data suggest a model in which the contribution to magnetic anomalies by the pillow basalt layer decreases with the age of the oceanic crust, though the contribution from the underlying dyke complex may not be susceptible to decay¹. The data also suggest that the credibility of the pillow basalt layer as the entire source of marine magnetic anomalies in old oceanic crust (at least 30 Myr BP) must be re-examined.

Field geological, petrological, geochemical, and marine geophysical data indicate that Macquarie Island (54° 15'S, 159°E) is an uplifted segment of late Tertiary (~ 30 Myr old) oceanic crust which was formed by seafloor spreading of the Australia–Antarctic Ridge^{2,3}. Pillow lavas exposed in the North Head region of Macquarie Island are relatively fresh and have not undergone burial metamorphism; however, pillow basalts exposed near Langdon Point have undergone significant burial metamorphism. Varne and Rubenach² have argued that this metamorphism is characteristic of the crustal accretion process at spreading oceanic ridges and is not the result of a metamorphic event associated with the tectonic uplift of Macquarie Island. This evidence indicates that the North Head exposures are representative of the upper (100–200 m?) portion of the oceanic basalt layer, whereas the Langdon Point lavas are from deeper oceanic crust ($> 1/2$ km deep?). To investigate the effects of burial metamorphism and seafloor weathering, oriented core samples were collected at 4 sites (nos 8–11) near Langdon Point and at 4 sites (nos 12–15) on the eastern coast of North Head.

Because of tectonic disturbance, NRM directions cannot be used for palaeomagnetic pole determinations but are very

useful in determining the presence of stable and viscous remanence at the sampling localities. The important mean parameters of natural remanence observed at both Macquarie Island sampling localities are summarised in Table 1. Directions of NRM for the Langdon Point sites show streaking toward the present direction of the axial dipole field at the sampling locality. On alternating field (a.f.) demagnetisation, the directions move away from the axial dipole direction. These observations indicate a significant component of viscous remanent magnetisation (VRM) in these metamorphosed pillow lavas. Experiments of the VRM acquisition confirmed the indication of a large viscosity coefficient, S , in samples from this locality. Directions of natural remanence at North Head sites show only a small tendency to streak towards the axial dipole field. Experiments on the acquisition of a.f. demagnetisation and acquisition of VRM also indicate that the unmetamorphosed basalts from North Head are not susceptible to large components of viscous remanence.

The geometric mean intensity of the NRM at both Macquarie Island sampling localities is surprisingly low. The geometric mean intensity is 0.69×10^{-3} gauss for samples from North Head and 0.57×10^{-3} gauss for Langdon Point samples (Table 1). In contrast, NRM intensities of some dredged samples have exceeded 10^{-1} gauss, and deep-tow magnetometer profiles over oceanic ridges also indicate a strongly magnetic layer of pillow lava in young oceanic crust^{4,5}. If the NRM intensity of these young pillow basalts does not decrease with depth into the oceanic crust, a thin (< 1 km thick) layer of strongly magnetic pillow basalts could account for the entire amplitude of marine magnetic anomalies. Seafloor weathering, however, causes low temperature oxidation of the magnetic minerals resulting in a decreased intensity of NRM^{6,7}. Data collected during the Deep Sea Drilling Project (DSDP) indicates that the upper pillow basalts of ancient oceanic crust have NRM intensities of $\sim 10^{-3}$ gauss^{8,9}. These values are in close agreement with NRM intensities of Macquarie Island pillow basalts, and are, perhaps, typical of old (> 30 Myr) oceanic crust in general. If that is the case, then the contribution of the pillow basalt layer alone is inadequate to account for magnetic anomalies observed over old oceanic crust.

From measurements of low field susceptibility, χ , the Koenigsberger ratio, Q ($= \text{NRM}/(\chi)(0.65 \text{ oersted})$), was determined for each sample. The mean Q value for North Head samples is similar to that observed in Atlantic DSDP basalts. The Langdon Point specimens show, however, a very high susceptibility and, consequently, a low Koenigsberger ratio. This high χ and low Q for Langdon Point samples indicates a difference in magnetic mineralogy between these metamorphosed pillow basalts and the unmetamorphosed pillows from North Head. Hysteresis properties for North Head samples indicate a distribution of magnetic grains which is predominantly within the single-domain range (R. F. B., S. K. B. and J. H. S., unpublished). By contrast, the hysteresis properties for Langdon Point samples indicate a substantial multi-domain (MD) content. This higher MD content would explain the higher magnetic viscosity coefficients in the Langdon Point samples.

Results of thermomagnetic analyses also indicate an important difference in magnetic mineralogy between the two Macquarie Island sampling localities. Irreversible thermo-

Table 1 Average parameters of remanent magnetism

Locality	Natural remanence (10^{-3} gauss)	Low field susceptibility (10^{-3} gauss oersted ⁻¹)	Koenigsberger ratio	Viscosity coefficient (10^{-5} gauss oersted ⁻¹)*
Langdon point (sites 8–11)	0.57	2.80	0.31	4.3
North Head (sites 12–15)	0.68	0.11	9.8	1.2

*Time measured in minutes.

magnetic curves were observed for all samples from North Head. An initial Curie temperature of between 300 and 400 °C was followed by an increase in magnetisation and a subsequent final Curie point between 500 and 580 °C. The saturation magnetisation after thermal cycling was always greater than the initial saturation magnetisation. This type of irreversible thermomagnetic behaviour has been observed in dredged pillow lavas⁷ and in DSDP basalts^{8,9}. The thermomagnetic results—and microprobe examinations of the opaque minerals (R. F. B., S. K. B. and J. H. S., unpublished)—indicate that the magnetic minerals in the North Head samples are non-stoichiometric titanomaghaemite. These cation-deficient phases are the products of low temperature oxidation resulting from prolonged seafloor weathering of the late Tertiary oceanic pillow basalts.

All of the Langdon Point samples show reversible thermomagnetic curves with a single Curie temperature very near 580 °C, indicating that the magnetic mineral in these metamorphosed pillow lavas is magnetite containing little or no titanium. Reversible thermomagnetic curves indicating Curie points of 580 °C have not been observed previously in analyses of dredged pillow basalts or DSDP basalts. This 'unusual' behaviour is almost certainly the result of burial metamorphism undergone by the Langdon Point basalts. The fine-grained titanomagnetites in young dredged pillow basalts are known to be very susceptible to chemical change when heated. At any significant depth in the oceanic crust pillow basalts would be exposed to heating by the intrusion of feeder dykes leading to overlying pillow lavas, the emplacement of underlying sheeted dyke and plutonic complexes, or even by exothermic hydration reactions within the metamorphosed pillow lavas themselves². Thus, the metamorphosed pillow lavas from Langdon Point and their resulting magnetic properties are thought to be the natural consequence of burial metamorphism experienced during seafloor spreading by basalts at significant ($> 1/2$ km?) depths in the oceanic crust.

The evidence from DSDP basalts, and the data presented here on pillow lavas from the North Head region of Macquarie Island indicate that the progressive submarine weathering of the oceanic crust decreases the NRM intensity of the upper portion of oceanic crust to $\sim 10^{-3}$ gauss. Lowrie, *et al.*⁸ have suggested that the 10^{-3} gauss NRM intensities of DSDP basalts are perhaps only representative of the strongly weathered zone at the top of the pillow lava layer and that unweathered pillow lavas below the weathered zone may be more strongly magnetised. But if the pillow lavas from Langdon Point on Macquarie Island are representative of pillow basalts from depths of 500–1000 m, the NRM intensity of these deeper extrusives would also be of the order of 10^{-3} gauss. Since a 1-km thick layer of pillow basalts magnetised at 10^{-3} gauss is not sufficient to yield the observed amplitude of marine magnetic anomalies, we conclude that the underlying basaltic and doleritic sheeted dyke complexes also contribute to the anomalies. Detailed analysis of changes in marine magnetic anomaly profiles with age of the underlying oceanic crust has led to a similar conclusion (R. J. Blakely, unpublished).

We thank Dr R. I. Garrod, Director of Antarctic Division, Australian Department of Science, and Dr R. Varne for assistance throughout this project. Assistance during field work was given by P. Williamson and P. J. Gloag; many of the sample measurements were done by Dave Bodgan and Jim Mellema. This project was funded by the National Science Foundation.

Effect of oxygen on aldolisation reactions

ALTHOUGH the kinetics of aldolisation reactions have been studied^{1,2}, no observations have been reported concerning the effect of oxygen on their rates and kinetics. We have studied polarographically the aldolisation of acetaldehyde in 1 M lithium hydroxide in the absence of oxygen and spectrophotometrically in the presence of air using absorbance at 230 and 277 nm. A difference in the concentration–time curves obtained using these two procedures was observed.

The base-catalysed autoxidation of ketones is probably³ initiated by the interaction of molecular oxygen with carbanions formed in alkaline media and in the past the observed discrepancy has, therefore, been attributed to the interaction of atmospheric oxygen with carbanions formed as intermediates in the course of aldolisation.

To test this hypothesis, we studied reactions of α -phenyl-substituted aldehydes of the type $RCH(C_6H_5)CHO$ in alkaline media. The pK values of these compounds⁴ are such that they exist in 1 M lithium hydroxide almost completely in the carbanion form. Observations of these compounds during kinetic runs showed that they behaved differently in the presence and absence of oxygen. In the absence of oxygen, polarographic and spectrophotometric measurements gave identical rates. As a side product of the reactions $RCOC_6H_5$ compounds are formed in the presence of air⁵, further confirming the reaction of carbanion with oxygen. The latter reaction has also been postulated as a side product of the oxidation of phenylacetaldehyde to benzoic acid⁶ and in association with the alkaline rearrangement of aconitine⁷.

Thus some discrepancies reported for the kinetics of aldolisation may result from an interaction between molecular oxygen and the carbanion intermediate. Consequently, in future studies of aldolisation and other reactions which involve carbanion formation, oxygen should be excluded completely.

Polymer drag reduction in Taylor vortices

THE Toms effect¹, whereby the addition of small quantities of polymer can typically produce 50% reduction in drag, occurs in turbulent flow systems. We report preliminary observations of a similar drag reduction behaviour observed in a Couette apparatus when toroidal Taylor vortices² are generated by rotating the inner of two concentric cylinders at sufficient speed; in this case the flow field is well understood and does not vary with time.

Simple shear alone as generated by normal Couette flow has little effect on deforming flexible polymer molecules and can be expected to exhibit no drag reducing effect; however, extensional flows such as pure shear, axial extension and compression do have the ability to extend molecules and the extensional viscosity when polymers are present may be orders of magnitude greater than the shear viscosity³. If this class of flow is present significant effects can be expected when polymers are added. In Taylor vortices the existence of extensional flow regions between each counter rotating vortex has already been

Fig. 1 Graph of torque as a function of angular velocity for a Couette apparatus 30 cm long, of inner cylinder diameter 2.0 cm and gap width 0.37 cm.

identified⁴ as the cause of nucleation of extended chain polymer crystals.

With a Couette apparatus we have measured the torque on the stationary outer cylinder using a fine torsion wire suspension. Figure 1 shows the torque measured for different rates of rotation of the inner cylinder using both water and polymer doped solutions. The polymer was polyethylene oxide (Union Carbide WSR301) of molecular weight $M_w \approx 4 \times 10^6$. The solution was renewed before each series of measurements to minimise the effect of possible shear induced degradation. For a low angular velocity of the inner cylinder when the flow is simple shear, the torque against ω curve obeys an essentially linear relationship for both solutions where the gradient of the line gives the shear viscosity, which is about 20% higher for the 50 p.p.m. polyethylene oxide (WSR301) water solution. At a critical speed (a in Fig. 1) the torque starts to increase non-linearly. This speed corresponds well with that predicted by Taylor² at which the secondary Taylor vortex pattern develops. Above this critical speed we assume that subsequent differences in the measured torque curve from the extrapolated straight line represent the additional drag caused by the secondary Taylor vortex flow. When Taylor vortices are well developed we see that the drag as measured by the torque is significantly reduced when polymer is present.

From our torque measurements we cannot say with precision

if there is a change in the onset of instability with the addition of polymer; however, our results do indicate that this change if present is not large. Changes in the onset of instability have been examined in detail by others⁵⁻⁸, however, these studies were confined to rates of rotation close to the critical region (a in Fig. 1). The large drag reducing effects we are concerned with, occur at greater rates of rotation well removed from this critical region.

By illuminating the gap between the two cylinders with a plane beam of light directed vertically along the radius and passing through the glass outer cylinder, the nature of the Taylor vortices could be examined in profile by observing scattered light from small tracer particles put into the solution.

Streamlines of the vortices observed at right angles to the incident beam are shown in Fig. 2. No detectable difference could be found in their profile with the addition of polymer, but examination of velocities using short time exposure photographs indicated that the speed of the vortices measured in a region where the vortices meet midway in the gap between cylinders, increased by up to 10% at $\omega = 13 \text{ s}^{-1}$ with the addition of polymer. This result is contrary to the expectations of some theories⁹ of drag reduction and indicates that drag reduction in Taylor vortices does not occur by suppression of vorticity; indeed the horizontal components of vorticity as represented by the secondary flow pattern of our experiments is enhanced.

We have shown that addition of polymer does not change significantly the onset of the secondary flow or suppress its vorticity and thus other mechanisms must be explored to explain the origin of the effect. We believe chain extension occurs near the cylinder walls in regions of compression where the vortex flow approaches either inner or outer wall. The possibility of

Fig. 2 Photographic profile view of Taylor vortex pattern generated in Couette apparatus; inner cylinder diameter 4 cm and gap width 1.0 cm.

chain extension occurring in the regions of extension where the vortices move away from the walls is not thought likely because related experiments firing a jet of polyethylene oxide solution at right angles to a flat surface showed localised birefringence corresponding to chain extension, near and parallel to the wall for jet outflow (axial compression) but no visible birefringence for the reverse flow direction when fluid was sucked into the jet (axial extension). We therefore conclude that in regions of compression in which chain extension occurs the extensional viscosity can be expected to increase significantly. As no drag reducing mechanism can be seen in the vertical plane we conclude that either the primary or secondary flow must be modified in the horizontal plane in such a way as to cause the reduction in overall momentum transfer to the outer wall. Further velocity profile and additional birefringence experiments viewing the horizontal plane of the Taylor vortex flow system will be carried out to establish this point.

At this stage certain generalisations concerning conditions for drag reduction may be proposed: an elongational flow system is required to produce chain extension; and the chain extension thus achieved should then be capable of reducing the momentum transfer (which is the cause of the drag) in a manner not specified in detail at the moment. This reduction of momentum transfer, however should not eliminate the elongational flow field which has produced the chain extension in the first place; its continued survival is a prerequisite for the whole effect.

Acoustic Bragg diffraction from human tissues

ANALYTICAL methods based on the use of ultrasonic beams are potentially of interest for the remote, *in vivo* characterisation of the mechanical structure of human tissues^{1,2}. We have investigated, from this point of view, the relationship, for a specific volume of tissue, between the recorded ultrasonic backscattering amplitude and the orientation of the tissue structure to the ultrasonic beam. Experimentally this measurement is closely analogous to Bragg's X-ray crystallography arrangement except that we use 180° backscattering geometry.

Our early observations suggested qualitatively that the acoustic Bragg traces obtained were indeed characteristic of the particular tissues examined³ and modelling calculations have shown that the data are consistent with the hypothesis⁴ that diffraction arises predominantly from the connective tissue microstructure of the organs involved, for example the lobular network in liver tissue⁵. Here we present quantitative evidence that the method can provide objective characterisation of tissue structure.

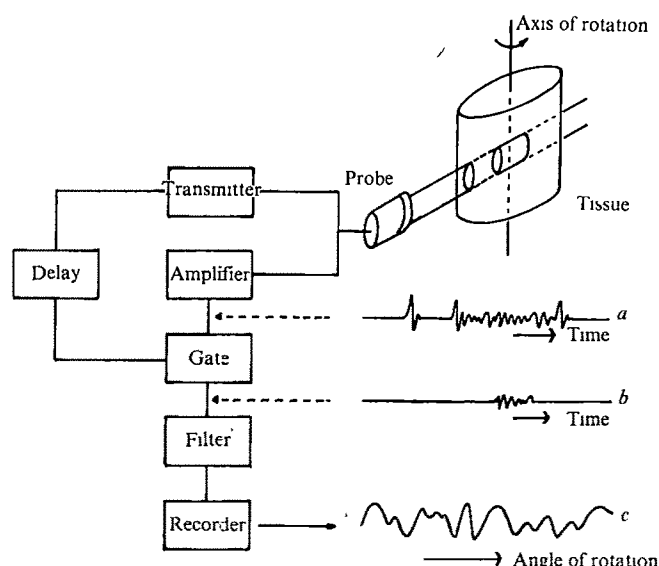

Fig. 1 Schematic diagram of the experimental arrangement for investigation of the backscattered Bragg diffraction characteristics of human tissues: *a*, received echo train from tissue specimens; *b*, gated output of received echo train; *c*, diffraction pattern obtained by frequency filtering the gated output while rotating the specimen.

Experimentally the apparatus is that of a conventional ultrasonic pulse-echo system (Fig. 1) in which an approximately cylindrical tissue specimen is positioned in a water-filled sound tank so as to lie directly in the sound beam, its long axis being normal to the direction of the beam. The sample is then rotated about this axis to enable backscattering amplitude measurements to be made from all angles. A time gate centred on this axis of rotation selects a portion of the returning echo train such that the total received echo amplitude corresponds to the backscattering from a specific volume of tissue, determined by the beam width, pulse length and appropriate time gate. Following frequency filtering of the returned echo train, plots of echo amplitude as a function of angle of rotation are obtained for one complete rotation. Some limited examples (0-50°) are shown in Fig. 2. An interesting feature of these diffraction patterns is that they seem to be characteristic of the particular tissue and presumably reflect corresponding differences between the respective tissue structures.

Evidently, several possible analytical approaches could be taken towards establishing the significance of differences or similarities between such traces and we report here the results of one of these, in which we have computed, by the fast Fourier transform method, the distributions of angular frequency

Fig. 2 Observed Bragg diffraction patterns from three types of human soft tissue, examined at 1.0 MHz. *a*, Liver; *b*, brain; *c*, spleen.

Fig. 3 Power spectra derived from the Bragg diffraction record of a specimen of human liver tissue, examined at 1.0 MHz.

components contained in the traces. A typical power spectrum obtained by this method from a single 'acoustic Bragg trace' has a somewhat complex structure, part of which may correspond to the 'picket-fence effect'⁶ inherent in the fast Fourier transform procedure (Fig. 3). For the purpose of investigating possible systematic differences between data from different tissues we have, therefore, smoothed the raw data in each spectrum by taking a seven-point average. Means of the smoothed power spectra have then been computed for each of the three sets of tissue specimens and these are plotted, together with their corresponding standard errors, in Figure 4.

These results demonstrate that this diffraction phenomenon observed in our initial investigations can be quantitatively related to the specific structure of the type of tissue. Although this finding is reasonable in view of the well known differences in the microscopic appearances of tissues of different types, its complete understanding in terms of the mechanical structure, including factors such as the existence of degrees of short range structural order, must be a subject for further research. Meanwhile, it suggests the prospect of a non-invasive diagnostic technique for distinguishing between different tissue structures *in vivo*, and thus depicting any pathological changes within a tissue region of diagnostic concern. An instrument designed to carry out such an *in vivo* investigation in the human liver has recently been constructed and will be described elsewhere.

We thank J. Milan for advice and assistance on various

Effect on mortality of the 1974 fuel crisis

THE 1974 fuel crisis was a natural experiment. It presented the opportunity to test the hypothesis that a decrease in vehicular exhaust fumes would have a beneficial effect on health. During the first quarter of 1974 retail gasoline sales were reduced by 9.5% in San Francisco and Alameda Counties, California. Total exhaust emissions were reduced by an even greater amount because of hoarding of fuel and lowered highway speed limits. To assess the possible effects of this selective decrease in pollution, mortality rates from these two counties were examined. The rates for the first quarter of 1974 were compared with corresponding rates from the first quarters of 1970-73.

Table 1 First-quarter mortality rates per 100,000 population in two California counties, 1970-74

	San Francisco County		
	1970-73	1974	% Decrease
All causes*	377.5	327.0	13.4
Cardiovascular disease†	128.8	107.3	16.7
Chronic lung disease‡	7.3	4.9	32.9
	Alameda County		
	1970-73	1974	% Decrease
All causes*	227.1	209.7	7.7
Cardiovascular disease†	84.2	74.8	11.2
Chronic lung disease	5.0	3.1	38.0

* Excluding all deaths from vehicular accidents

† For reasons of data availability, this category includes acute myocardial infarction and chronic ischaemic and arteriosclerotic heart disease in Alameda County and all cardiac deaths in San Francisco County

‡ Includes chronic bronchitis, asthma and emphysema.

Dramatic decreases were noted in death rates for several major categories of disease (Table 1). These included all causes combined (with vehicular accident deaths excluded); pooled cardiovascular deaths; and deaths from asthma, chronic bronchitis and emphysema (denoted as "chronic lung disease"). Rates for the comparison years have been combined for simplicity of presentation. It should be noted, however, that the rates for those years were rather homogeneous. For the disease categories studied, the 1974 first-quarter rates were lower than any of the 1970-73 first-quarter rates. The 13.4% decrease in all-cause mortality in San Francisco, the more urbanised county, was almost twice that in Alameda County (7.7%). The disease category showing the greatest relative change was chronic lung disease.

In general, when the data were analysed by age, the greatest change occurred in the under 45 age group, and the least change among those over 65. We believe that this may be a result of differential exposure. Both sexes showed decreased mortality.

There was no first-quarter secular trend during the period

1970–73 for those disease categories examined. Consideration of the time trend for all quarters in San Francisco revealed a relatively repetitious and predictable seasonal variation with sharp upward swings in winter quarter death rates. During the period January 1, 1969–March 31, 1974, this cyclic trend was interrupted only by the sharp decline in mortality during the first quarter of 1974. Analysis of weather and air stability data, relevant pollutant levels and the pattern of influenza and pneumonia deaths (sometimes thought to influence cardio-respiratory deaths) support the hypothesis that a decrease in vehicular exhaust fumes would have a beneficial effect on health.

It is important that these data be analysed further and in more detail. Such analyses will include comparison of mortality rates in urban–rural subdivisions of Alameda County, consideration of the seasonal and secular trend in Alameda County for the period 1970–74, examination of several other causes of death (particularly those causes not expected to be affected by air pollution) as well as analysis of mortality data in the period following the crisis.

Sweeping flight and soaring by albatrosses

ALBATROSSES can fly over the sea for a long time without flapping their wings. Raleigh¹ worked out a suitable method, known as dynamic soaring, to account for this and Idrac² showed that this was the method used by the birds.

Dynamic soaring makes use of the gradient in wind velocity near the surface of the sea. The bird gains energy by climbing into the wind: as it climbs it loses forward speed, but it gains airspeed by rising into the faster winds at the higher levels. It can continue to climb for as long as the wind velocity gradient is sufficient. Similarly, the bird can gain energy by losing height downwind. Combining these manoeuvres it is able to maintain flight, climbing upwind and gliding downwind in a series of swoops³.

I have suggested⁴ another method which could be used by albatrosses either in combination with dynamic soaring or as an alternative to it. Here I present calculations and a computer simulation showing that the method can provide enough energy for sustained flight.

Albatrosses often fly along the flanks of waves. This was observed by Idrac², who did not attribute any importance to it. He remarked elsewhere that he had found rising air currents directly related to the waves, in some cases greater than 2 m s^{-1} at 8 m above the sea and still detectable at 15 m. He did not think that the albatross made any use of these variations in the airflow except in exceptional cases, but they would be available for the method of soaring proposed here. It has been proposed that the birds do make incidental use of these updrafts. Pennycuik⁵ writes that "the birds use 'static' soaring along waves combined with dynamic soaring in a rather intricate way". Jameson⁷ says more specifically that the birds may use "the strong updrafts near the crests of the wave to gain considerable height—an initial kick-off, as it were, of 10 or 15 feet . . . the bird making only incidental use of the rising air currents close above the waves . . ."

The method which I propose is this static soaring to provide the initial 'kick-off', but by specifying the method more accurately it can be seen that it is more powerful than had been suspected.

The bird would take off from the crest of a wave and position itself in the rising current against the flank of the wave, maintaining this position in gliding flight. In still air, it would lose height, but in air which is rising over the wave it could maintain height by slope-soaring or could even gain height. Alternatively, it could use the upcurrent to gain speed. It could sweep along the flank of the wave, staying in the strongest upcurrents close to the surface. When the speed is sufficient, or when the bird reaches the end of the wave, it could use the speed by soaring upwards. It could then glide freely in any direction, losing height gradually until it again become necessary to swoop down and fly against the flank of a wave. Thus flight could be maintained indefinitely. This method of soaring, I shall call sweeping flight.

The height to which a bird can zoom out of slope lift can be calculated if the flight polar of the bird and the strength of the lift are known. The flight polar expresses the relationship between the flying speed V of the bird and its sinking speed S in still air. Usually, as flying speed increases the sinking speed will increase at an accelerated rate. A relatively flat polar would express the ability of the bird to fly at high speeds while maintaining a low rate of sink.

Height can be maintained by flying in air which is rising at a rate to match the sinking speed of the bird. If the bird flies close to the water in slope lift (air rising over a wave), it can increase its flying speed until its sinking speed matches the upward velocity of the air. Thus for any given upflow we can read off directly from the polar the maximum speed V_2 which the bird can reach without losing height.

Flying speed can be converted into height by climbing rapidly. If the bird can remain under control down to some minimum gliding speed V_1 , then its excess kinetic energy is given by $E = \frac{1}{2}m(V_2^2 - V_1^2)$, where m is the body of the bird. Neglecting drag, which is relatively small, the whole of this kinetic energy can be converted to potential energy by soaring to a height h . Thus:

$$h = E/mg = (1/2g)(V_2^2 - V_1^2)$$

A greater height can be reached in a wind gradient by climbing against the wind and so making use of dynamic soaring, but I shall now neglect dynamic soaring and consider only the height which can be reached by sweeping flight alone.

A bird with a flat polar will be able to reach a high speed in a relatively light upcurrent, and will be able to climb to a greater height. Birds with a flat polar will be well suited aerodynamically to the method of flight described here, whereas those with a steep polar will not be able to use it at all. This requirement, of a flat polar, is the same as that for dynamic soaring, so that a bird which is suited to one method would be suited to the other and the two methods could easily be used in combination or alternatively. Dynamic soaring could be used when the wind gradient extends up to a suitable height, perhaps 20 m; sweeping flight could be used when winds are strong but the wind gradient is not suitable.

Albatrosses, with their long narrow wings, must have a relatively flat polar, but accurate data are difficult to obtain. Bramwell and Whitfield⁸ give a curve derived from scanty data by Schmitz¹²; this was the polar used in my computer simulation. Wood⁹, for his computer simulation of dynamic soaring, used a standard aerodynamic formula with constants derived from Lanchester's¹⁰ figures for weight and wing measurements of an immature specimen of *Diomedea exulans*. This formula gives a polar closely parallel to that of Bramwell and Whitfield, but with about 0.2 m s^{-1} less sink. Thus, using the Bramwell and Whitfield polar gives a conservative estimate of performance on sweeping flight, as compared with Wood's simulation of dynamic soaring.

For waves of steepness $1/12$ and a wind of 6 m s^{-1} , the upcurrent near the wave is 1.65 m s^{-1} . This is not unrealistic, since Idrac observed even greater upcurrents in association with waves. On the Bramwell and Whitfield polar, 1.65 m s^{-1}

of sink corresponds to a flying speed of 23 m s^{-1} , and it seems that the bird can still fly at speeds of about 12 m s^{-1} . Thus, $h = 19.7 \text{ m}$. This is considerably greater than the 10 or 15 feet suggested by Jameson, and indicates that the method would be a practical one.

To obtain a more realistic estimate of performance, a program was written to simulate the sweep method of soaring on a computer. It was assumed that the wind velocity does not vary with height, and that the flow of air follows the (water) waves at the surface, so producing a sinusoidal vertical component of wind velocity; this component reduces vertically with height, reaching zero at twice the wave height. Performance is monitored by showing wave and bird on a display screen, and the print out shows flying speeds, height reached, cycle period and so on.

The simulation was run for various wind velocities and the results are shown in Fig. 1. Wave height was kept constant at 3 m. (Wave height is relatively unimportant, except in respect of giving space to manoeuvre, since wavelength tends to vary with wave height so leaving wave slope invariant.)

Fig. 1 Performance of four gliders using the method of sweeping flight. ●, Albatross; ■, *Pteranodon*; ♦, fulmar petrel; ▲, glider Ka6CR.

At low wind velocities ($< 3.2 \text{ m s}^{-1}$), the upcurrents are insufficient to sustain even minimum-sink gliding flight during the sweep. The bird stalls and the flight is terminated. With slightly higher wind velocities the sweep can be maintained but flying speed is increased only slightly, since the increased sinking speed of the bird soon matches the upward velocity of the air. In such cases the simulation gives short sweeps punctuated by small hops. At still higher wind velocities, the flying speed can be increased substantially during the sweep and the bird then climbs to a useful height, comparable with heights observed in practice. Maximum height reached is 26 m, with a maximum period of 62 s.

The simulation was also run with polars for the fulmar petrel, the Cretaceous flying reptile *Pteranodon* and a glider. The glider needs far more wind than the albatross to remain airborne, but far outperforms the bird at high wind velocities. The calculation is unrealistic, however, since it ignores the difficulties of placing a large glider between the waves.

The polar for the fulmar petrel *Fulmaris glacialis* was obtained by Pennycuik from measurements using a cine-camera

technique⁵. Though neither the albatross data nor those for *F. glacialis* are claimed to be accurate, it is clear that the fulmar has a greater sink at all speeds of which it is capable, and its polar is much steeper than that of the albatross. The simulation shows the fulmar reaches a maximum height of only 8 m.

The polar for *Pteranodon* was obtained by Bramwell and Whitfield from wind-tunnel measurements of a model⁶. Again, the figures cannot be claimed to be accurate, but provide a working estimate. With this polar, the simulation shows *Pteranodon* as reaching a maximum height of 7 m.

Pennycuik concluded for *F. glacialis*, and Bramwell and Whitfield for *Pteranodon*, that they were primarily slope-soarers and were unsuited to dynamic soaring. They are also far less suited to the suggested method of sweeping flight than is the albatross.

I thank Dr Colin Pennycuik for his comments and suggestions, and John Lazarus for some useful references.

Localisation of human peptidase-A structural locus from studies on a cultured lymphoblastoid line

LONG term genetic analysis of lymphoblastoid cell lines provides a practical means of studying the types of spontaneous and induced mutation that can occur in human somatic cells^{1,2} and of following the evolution of distinct populations of cells within a bulk culture^{3,4}. Occasionally, data may be expected to emerge which facilitate the localisation of human structural genes. We now report the first such application of this technique.

The human lymphoblastoid cell line F137 (ref. 5) has been maintained in Edinburgh since 1969 and more than 200 clones have been grown (sometimes after treatment of the bulk culture with mutagen) from single cells plated out in individual wells of plastic culture plates^{1,4}. The parent line has been examined at intervals for the electrophoretic pattern of more than 30 isoenzymes and each clone, when it has reached a sufficient cell number (usually within 2 months of isolation) has been analysed in the same way¹. Chromosome preparations have been made from both parent line and clones and analysed after staining with quinacrine dihydrochloride⁶⁻⁸.

The original F137 line was heterozygous at the pep-A locus¹ with the phenotype pep-A-2-1. In an early series of experiments (May 1971), one clone, A56 (ref. 1), seemed to be hemizygous for pep-A-2. Over the next three years, a further 133 clones were isolated from the original line; 14 had the pep-A-2 phenotype, two had an asymmetrical electrophoretic pattern with partial loss of the pep-A-1 band, and the remainder had the original symmetrical pep-A-2-1 pattern⁴. Quantitative assay of peptidase-A confirmed that loss of the pep-A-1 electrophoretic band was associated with a 50% reduction in enzyme activity⁴.

Human lymphoblastoid cell lines are not entirely stable with respect to chromosome constitution, and various rearrangements can be detected when cultures are re-examined at intervals over a period of years^{1,3}. The modal karyotype of the F137 line during the period of this study was 47, XY, the extra chromo-

Fig. 1 Chromosome pairs 4, 9 and 18 from quinacrine-stained metaphase spreads representative of the parent line F137 (*a*), clone H₅ (*b*), clones with a 9/18 translocation (*c*) and those with a 4/18 translocation (*d*). Clones with the aberrations shown in *b* and *c* have lost activity of the pep-A-1 allele. The 4/18 translocation (*d*) is not associated with any change in pep-A phenotype.

some being a small submetacentric marker about the size of a chromosome 17/18 but distinguishable from them on quinacrine fluorescence.

The original pep-A-2 clone (A56; ref. 1) was lost before it could be examined cytogenetically. Chromosome analysis has been carried out on all subsequent clones showing alterations in the expression of the pep-A gene and on 84 of the 116 clones isolated over the same period which have retained the symmetrical pep-A-2-1 phenotype. From 4–30 metaphase spreads have been photographed and fully analysed from each clone.

Table 1 and Fig. 1 demonstrate the complete relationship between certain chromosome rearrangements involving chromosome 18 and changes in the pep-A phenotype of individual clones. One pep-A-2 clone (H₅) differed from the modal karyotype of the parent line only in having a deletion at the mid-point of the long arm of one chromosome 18 (Fig. 1*b*), a finding which supports the previous assignment of the human pep-A

Table 1 Pep-A phenotype and aberrations involving chromosome 18 in one hundred clones of F137*

Pep-A phenotype	Aberrations involving chromosome 18			
	No abnormality	4/18 translocation	9/18 translocation	18q-18q-
2-1	59	25	0	0
2	0	0	15†	1

* One isolate with an asymmetrical pep-A-2-1 pattern is excluded as not being a true clone but a mixture of cells with a 9/18 translocation and those with the F137 modal karyotype.

† Includes clone J28 with 10% pep-A-1 activity.

structural locus to the distal half of the long arm of chromosome 18 (refs 9–12).

The other 13 pep-A-2 clones all had an identical translocation (Fig. 1*c*) in which almost the whole of the long arm of one chromosome 9 was fused with the long arm of an 18, the point of fusion being marked by an intercalary band of heterochromatin from the centromere region of the 9 (Figs 1*c* and 3).

None of the 84 pep-A-2-1 clones examined contained any cells with the 9/18 translocation. Thirty-one had a karyotype identical to that of the modal cells of the parent line and 38 showed minor variations, most of which had been recognised in the parent line⁴. A further 25 had the rearrangement shown in Fig. 1*d* (cells of this type were also represented in the parent line in February/March 1973). In this case there was a break at the distal end of the long arm of a number 18 with a translocation on to it of approximately half the long arm of a number 4.

As Fig. 2 demonstrates, the break points on the long arm of chromosome 18 are indistinguishable in the 9/18 and the 4/18 translocations described above, yet in one case activity of the pep-A gene is lost, whereas in the other it is retained. Attention is therefore directed to the possible role of the translocated centromeric heterochromatin from chromosome 9.

Fig. 2 Diagrammatic representation of the rearrangements involving chromosome 18 in the series of clones described in text. The break point on chromosome 18 involves the q23 region in both cases. The origin of the long arm material distal to the centromeric heterochromatin on the deleted chromosome 9 is uncertain.

Fig. 3 C-banded preparation¹⁸ of cell from a pep-A-2 clone. The intercalary heterochromatin on the 18/9-derived chromosome is readily seen. There is some reduction in the amount of centromeric heterochromatin on the deleted chromosome 9.

In *Drosophila*, inactivation of a structural locus as a result of autosome-autosome translocation has been attributed to the suppressive effect of adjacent heterochromatin^{13,14}. (Similar gene suppression occurs when material from an autosome is translocated on to the inactive X chromosome in the mouse¹⁵.) It is usually varied in its incidence in individual cells, resulting in a variegated phenotype; further evidence that the locus in question is inactivated rather than deleted is provided if there is frequent reversion to give mosaicism or if reversions occur after recombination in which the affected locus and the adjacent heterochromatin become separated¹⁶.

One of the clones included in this study (J28) showed a very weak band in the pep-A-1 region, corresponding to approximately 10% of the normal pep-A-1 activity. On chromosome analysis every one of 30 cells examined had the 9/18 translocation shown in Fig. 1c. It is possible that this was an example of partial reactivation of the suppressed locus, although contamination with a few cells lacking the 9/18 translocation has not been completely ruled out. A second sample of this clone examined 1 month after recovery from storage in liquid nitrogen showed no detectable pep-A-1 activity.

Further studies are in progress with the aim of detecting revertants, with or without further chromosome change, in this and other pep-A-2 clones. If found, they will establish that a 'position effect' on human gene expression has been demonstrated for the first time.

Two other possible explanations for the present findings must be considered. First, since the distal fragment of the broken 18 is too small to be identified, it is possible that there has been reciprocal translocation, with retention of this fragment, in the 4/18 rearrangement but not in cells with the 9/18 translocation. Second, the break points of the 18 long arm may not be identical, being proximal to the pep-A-locus in one case but distal to it in the other. All three interpretations place the human pep-A structural locus, with some precision, in the q23 region of chromosome 18 (Fig. 2).

By virtue of their indefinite lifespan *in vitro* and their re-

lative genetic (including cytogenetic) stability, cultures of human lymphoblastoid cell lines offer considerable scope for further mapping of the human karyotype, particularly if data can be accumulated centrally from a number of laboratories over a prolonged period¹⁷.

Regulation of chromosome 21-directed anti-viral gene(s) as a consequence of age

WHEN human fibroblast cells are cultured *in vitro* they undergo about 50 cell population doublings at which time their growth rate begins to slow down and they finally die^{1,2}. For this reason, several investigators have used the senescence of human fibroblasts *in vitro* as a model system for experimental ageing research³⁻⁶. One explanation for human fibroblast senescence is that some cell functions are lost before cells reach their maximum division limit. We have described the existence of a complex regulatory gene function controlling the inducibility of chromosome 21-directed anti-viral gene(s) (AVG) in human fibroblasts⁷. Our conclusions were derived from experiments on human fibroblasts monosomic, disomic or trisomic for chromosome 21. We therefore used all three cell types in this study to test the preservation of this complex regulatory gene function in fibroblasts allowed to age *in vitro* and in fibroblasts derived from human donors of different ages. We found (1) that no differences exist in AVG expression in human fibroblasts allowed to age *in vitro* and (2) that the AVG in human fibroblasts derived from older human donors (64 yr) is easier to induce than it is in younger donors (0-29 yr).

Human fibroblasts trisomic (T-21), disomic (D-21) and monosomic (M-21) for chromosome 21 were cultured in 75-cm² Falcon flasks and maintained with Eagle's medium containing 10% heat inactivated foetal calf serum and 1% glutamine. The cultured cells were split at a 1:4 ratio every week for 8 months. Each split is designated as a passage number so, for example, cells split during week 15 are referred to as passage 15 cells.

Table 1 Inducibility of anti-viral gene(s) in human skin fibroblasts at different cell passage

Age of donor (yr)	Cell type	No. of cell population doublings	Units HuIF required to inhibit viral RNA synthesis by 50%

		66*	0.015, 0.018
		68†	0.017

In those cases where more than one value is given, the additional values represent experiments done on different days.

* Cell growth in phase III.

† No cell growth.

Each passage number is equivalent to two cell population doublings (passage 15 cells would have undergone 30 cell population doublings). The cells from one to two confluent flasks were frozen at each passage and stored in liquid nitrogen. The frozen cells were subsequently recultured and induced with human interferon. Concurrently the rates of cell growth were monitored at monthly intervals to determine the onset of cellular senescence. In all cases the rate of cell growth began to decrease by the time the cells had undergone 40–60 cell population doublings.

Normal diploid fibroblasts at different cell passage numbers were induced with various concentrations of human interferon. The inducibility of the AVG in these cells was assessed by the amount of human interferon required to inhibit viral RNA synthesis by 50% (ref. 7). Table 1 shows that the inducibility of the AVG remains unchanged in normal diploid fibroblasts in spite of ageing *in vitro*. Presumably this means that the regulatory gene function(s), known to control the inducibility of the AVG, also remains the same. The existence of a regulatory gene

Fig. 1 Gene dosage effect of chromosome 21 on the inducibility of the AVG in human fibroblasts monosomic, disomic and trisomic for chromosome 21. Each point represents the mean reciprocal concentration of human interferon required to induce the AVG in these cells and are derived from the values in Table 1.

function was previously demonstrated by the dosage effect of chromosome 21 on the amount of AVG product⁷. For this reason, the dosage effect of chromosome 21 on the inducibility of AVG was retested in early and late passage human fibroblasts containing differing numbers of chromosome 21. The results in Table 1 show that the dosage effect of chromosome 21 on the inducibility of the AVG remains unchanged in early and late passage M-21, D-21 and T-21 fibroblasts. These results were also plotted semi-logarithmically and a straight line represented by the equation, $\log Y = 0.6X$ (where Y denotes inducibility of the AVG and X denotes the number of chromosome 21 present) was obtained (Fig. 1). Previously, a dosage relationship expressed by the equation $\log Y = 0.61X$ was obtained⁷. The similarity in the two determinations suggests that there is no measurable loss of inducible AVG function and no significant change in the regulation of AVG expression in fibroblasts which have become senescent *in vitro*.

In the absence of measurable differences between early and late passage human fibroblasts we decided to compare the inducibility of the AVG in fibroblasts derived from human donors of different ages. In the following experiments, fibroblasts obtained from young humans (0–29 yr) are arbitrarily designated young fibroblasts and those from old humans (64 yr) are designated old fibroblasts. These fibroblasts were induced with various concentrations of human interferon and the inducibility of the AVG in these fibroblasts is presented in Table 2. The concentration of interferon required to induce the AVG in old fibroblasts is 2–3-fold lower than that required to induce the AVG in most of the young lines tested. One exception was a fibroblast line (GRC 35) derived from a 26-yr-old male which was shown to require about the same concentration of human interferon to induce the AVG as old fibroblasts. At

present such exceptions are difficult to explain. They may represent variant forms with enhanced sensitivity to the anti-viral action of interferon. The observed differences in the inducibility of the AVG in old and young fibroblasts suggest, however, that the structural gene element(s) which codes for the putative anti-viral protein or the receptor site for interferon are not as strongly repressed in old fibroblasts as in young fibroblasts. Others have also proposed similar mechanisms to explain the differential sensitivity of old and young chick embryo fibroblasts to chick interferon^{8,10}. This raises the question as to what cellular mechanisms are responsible for the differences in the different degrees of gene repression. One possibility may be that a nonspecific "relaxation" or "disorganisation" of the human genes occurs as a consequence of

age. Alternatively there may be selective pressures during the normal life span favouring the selection of cells based on their sensitivity to the anti-viral action of interferon.

It is apparent from this study that the regulatory gene function(s) controlling the inducibility of the AVG is not significantly changed in cells as a result of *in vitro* cell age.

Mitochondrial suppressor of a nuclear gene in *Paramecium*

THE biogenesis of mitochondria depends on two sources of genetic information: one in the nucleus and the other within the mitochondria. An important question raised by this situation is how information from the two sources becomes integrated to form a functional organelle^{1,11}. Products coded by both mitochondrial and nuclear DNA have been shown to be assembled in the mitochondrial inner membrane to form complex enzymes such as ATPase, cytochrome oxidase, cytochrome *b* and mutations in either genome can affect enzyme activity^{2,6,7,14}. Since the activity of such enzymes depends on molecular interactions between their component subunits, it is conceivable that a defect in one subunit can be, at least partly, corrected by a mutation affecting another subunit. A nuclear mutation suppressing the effect of a mutated mitochondrial gene has been studied in *Neurospora*⁸. We report here the reverse situation.

The mutation was isolated in *Paramecium tetraurelia*, according to the new nomenclature¹³ and formerly *P. aurelia*, syngen 4. It is a mitochondrial mutation that partially suppresses the effects of the nuclear mutation *cl*₁. The properties of this mutation *cl*₁, already described¹⁰ are summarised first.

*cl*₁ is a monogenic nuclear recessive mutation and is characterised by (1) slow growth—a generation time of about 9 h at 27 °C instead of 6 h for wild type; (2) thermosensitivity—

most of the mutant cells die at 36 °C whereas the wild type grows as well as at 27 °C; (3) spectral deficiency in cytochrome oxidase—the absorption peak at 608 nm is about 10 times lower than in wild type; (4) incompatibility with mitochondria of wild-type origin (*M*⁺) and compatibility with those of mutant origin (*M*^{cl}): in contrast to the association between *cl*₁/*cl*₁ nucleus and *M*^{cl} mitochondria, the association *cl*₁/*cl*₁*M*⁺ results in a very reduced growth rate (generation time 15–20 h) and severely disorganised mitochondria. Although the basis (genetic, physiological or structural) of the difference between *M*⁺ and *M*^{cl} remains to be established^{3,10}, the *M*⁺ and *M*^{cl} states of mitochondria are stable and can be used as mitochondrial markers.

From the original *cl*₁ strain, a spontaneous fast growing revertant, *cl*₁-su, was isolated: its generation time at 27 °C is nearly that of wild type (7 h), although its amount of spectroscopically detectable cytochrome oxidase is not significantly different from that of the *cl*₁ mutant and its thermosensitivity is unchanged.

To establish the nature of this revertant, it was crossed with the wild type (Fig. 1A). The analysis depends on certain favourable features of the genetics of *P. tetraurelia*. The cyto-genetic events of conjugation result in identical nuclear genomes in the F₁ clones derived from each ex-conjugant¹². Commonly, cytoplasm is not passed from mate to mate and so, the two clones arising from a pair of conjugants are like a pair of reciprocal crosses. In the cross performed here, therefore, one derives its cytoplasm from the wild type, the other from the revertant parent. The second generation is obtained from the F₁ clones by autogamy; if autogamy occurs in a clone heterozygous for a pair of nuclear alleles, 50% of homozygote cells for each allele are obtained in F₂ (ref. 12).

The results of the cross between the revertant (*cl*₁-su) and wild type (*cl*₁⁺), summarised in Table 1, reveal: (1) a 1:1 segregation in F₂ of the thermosensitivity property; (2) a difference between the two reciprocal crosses, ♀*cl*₁-su × ♂*cl*₁⁺ and ♀*cl*₁⁺ × ♂*cl*₁-su, as judged from the growth rate: a 1:1 segregation of slow-growing against normally growing cells appears only in the F₂ of the wild type cytoplasmic line. The phenotype of these slow growing cells clearly shows that the original *cl*₁ mutation was present and unchanged in the revertant: they have the typical generation time (15–20 h), thermosensitivity and mitochondrial alterations of the *cl*₁/*cl*₁*M*⁺ cells¹⁰. In the *cl*₁-su cytoplasmic line, the segregation of the alleles *cl*₁ and *cl*₁⁺ is only expressed by the segregation of the thermosensitivity character.

At least two hypotheses could account for these results: (1) the reversion could be due to a nuclear suppressor mutation. If so, it would have to be closely linked to *cl*₁ and would only suppress the slow growth of the *cl*₁/*cl*₁ cells when associated with *M*^{cl} mitochondria but not the interaction between gene *cl*₁ and *M*⁺ mitochondria. (2) The reversion could be due to a cytoplasmic suppressor (su). To test this second hypothesis the following experiment was carried out: the original *cl*₁/*cl*₁ strain, without suppressor, that is su⁺, was crossed with a *cl*₁⁺/*cl*₁⁺ strain derived from the *cl*₁-su cytoplasmic line of the previous cross (Fig. 1B), which was assumed to carry the

Table 1 Cross between the revertant (*cl*₁-su) and wild type (*cl*₁⁺)

Parents	Parental phenotype		F ₁ phenotype		Generation time (h)	F ₂ phenotype	No. of clones
	Generation time (h)	Thermo-resistance	Generation time (h)	Thermo-resistance		Thermo-resistance	
Revertant (<i>cl</i> ₁ -su)	7	—	6–7	+	7	+	58
					7	—	62
Wild type (<i>cl</i> ₁ ⁺)	6	+	6	+	6	+	73
					15–20	—	76

In the last column, the figures indicate the number of F₂ clones (from three different couples) studied. Average generation times at 27 °C are given. Thermoresistance or thermosensitivity at 36 °C is indicated by + or —. The cytoplasmic origin of each exconjugant F₁ clone was determined by its mating type, which is cytoplasmically inherited in this species¹².

postulated cytoplasmic suppressor, that is, su. Moreover, to test by this same cross whether the suppressor was mitochondrial or not, mitochondria from one parent (cl₁/cl₁) were marked by erythromycin resistance (M⁺E^R), those of the other (cl₁⁺/cl₁⁺) by erythromycin sensitivity (M⁺E^S). This is critical for the analysis, because it is possible in *Paramecium* to obtain matings in which cytoplasm (and mitochondria) of each mate pass to some extent into the other (Fig. 1B, b), so that each resulting clone has a mixed mitochondrial population (M⁺E^R + M⁺E^S). According to the medium (erythromycin or normal) in which these mixed clones are grown, one or the other type of mitochondria is selected^{1,9}. In this way, it is therefore possible to demonstrate whether the suppressor is associated with the mitochondria.

Two types of pairs were studied as explained in the legend of Fig. 1B; those without and those with cytoplasmic exchange between the two conjugants. Results obtained in F₂ for clones a1, a2, b1-1, b1-2, b2-1, b2-2 are given in Table 2. When no cytoplasmic exchange occurred between the two conjugants (pair a), 50% of cl₁/cl₁ cells (same generation time, 11 h, as the cl₁/cl₁M⁺E^R parent) and 50% of cl₁⁺/cl₁⁺ cells (generation time: 6 h) were obtained from the ex-cl₁ conjugant (a₂); all of these cells were E^R. In contrast, no segregation was apparent from the ex-cl₁⁺ conjugant (a₁): all the F₂ clones had a generation time of about 7 h and were E^S. This result means,

Fig. 1 Genetic analysis of the revertant. A, Cross between the revertant (cl₁-su) and wild type (cl₁⁺). ●, Cytoplasm of the revertant; ○, cytoplasm of wild type; ○, nucleus of the revertant; ●, nucleus of wild type; During conjugation, the reciprocal exchange of nuclei between the two parents yields two exconjugants (F₁) of identical heterozygote genotype ●, which differ only in their cytoplasm and therefore correspond to the two reciprocal crosses: ♀cl₁-su × ♂cl₁⁺ and ♀cl₁⁺ × ♂cl₁-su. Each exconjugant yields a clone and 20 generations later, autogamy can be induced in all cells of these F₁ clones. Autogamous cells then undergo a nuclear reorganisation which renders them homozygous for all their genes. If autogamy occurs in a clone heterozygous for a couple of nuclear alleles, a 1:1 ratio of the two homozygous genotypes is obtained in F₂ (ref. 12). B, Cross between a cl₁⁺/cl₁⁺ strain (●) derived from the revertant parent (●) and a cl₁/cl₁ strain (○) whose mitochondria carry a mutation for erythromycin resistance (M⁺E^R). This E^R mutation was selected from the original mutant strain which did not contain the suppressor (su⁺). From this cross, a pair (a) which had not undergone cytoplasmic exchange was studied as well as a pair (b) which had undergone a cytoplasmic bridge of 20 min. After the first post-conjugal fission in normal medium, one cell from each exconjugant was placed in erythromycin (150 γ ml⁻¹) (E), the other was maintained in normal medium (N): as a result, clones b1-1 (after a lag of 2-4 d) and b2-1 became pure for M⁺E^R mitochondria, and clones b1-2 and b2-2 for M⁺E^S mitochondria. The F₂ analysis of these clones is given in Table 2.

therefore, that the cytoplasm of the cl₁⁺ strain did carry the suppressor and maintained it over 120 cellular generations of association with a wild-type genotype (Fig. 1B). Furthermore, it can be seen that this suppressor also suppresses the incompatibility between gene cl₁ and mitochondria from the wild type, for the cl₁/cl₁M⁺su cells have a generation time of 7 h.

Information concerning the mitochondrial location of the suppressor can be derived from the study of the exconjugants which have exchanged cytoplasm (pair b). The presence of the suppressor in these exconjugant clones can be determined by the growth rate of the F₂ cl₁/cl₁ cells derived from them.

The mitochondrial composition of these clones (containing both M⁺E^R and M⁺E^S mitochondria after conjugation) will depend on the medium (E or N, Fig. 1B) in which they will be put, one fission after conjugation. In erythromycin, they will become pure for E^R mitochondria, in normal medium, pure for E^S ones^{1,9}. A very strict correlation between the presence or the absence of M⁺E^S mitochondria and the presence or the absence of the suppressor was observed (Table 2). When the F₂ progeny of a clone is E^S (b1-2), the generation time of the cl₁/cl₁ cells is identical to that of the cl₁⁺/cl₁⁺ ones and therefore the suppressor is present. When the F₂ progeny is E^R (b1-1 and b2-1), the generation time of the cl₁/cl₁ cells is 11 h: the suppressor is absent. The joint loss of E^S mitochondria and of the suppressor in clone b1 is particularly striking. Conversely, the joint gain of the E^S mitochondria and of the suppressor was observed in clone b2-2. While clones b1-1, b1-2, b2-1 had become pure for one mitochondrial type, clone b2-2 was still mixed (M⁺E^Rsu⁺, M⁺E^Ssu⁺) when autogamy occurred: this was shown by the intermediate growth rate and resistance to erythromycin of the 13 cl₁/cl₁ cells when they were first tested (Table 2). Five fissions after autogamy, cells from these 13 clones were still mixed and could become pure for either E^R mitochondria and the su⁺ condition (generation time: 11 h)

Table 2 F₂ progenies of the cross cl₁⁺/cl₁⁺ M⁺E^S su × cl₁/cl₁ M⁺E^R su⁺ after growth in erythromycin (E) or normal medium (N) of the F₁ clones

F ₁ clones	a1 (N)	a2 (N)	b1-1 (E)	b1-2 (N)	b2-1 (E)	b2-2 (N)
Genotype	cl ₁ /cl ₁	cl ₁ ⁺ /cl ₁ ⁺	cl ₁ /cl ₁	cl ₁ ⁺ /cl ₁ ⁺	cl ₁ /cl ₁	cl ₁ ⁺ /cl ₁ ⁺
Generation time (h)	7	11	11	6	11	6
Erythromycin resistance	-	+	+	-	+	+
No. of clones	85	39	14	15	30	13

The origin of the clones a1, a2, b1-1, b1-2, b2-1, b2-2 is given in Fig. 1B. The F₂ cells (cl₁/cl₁ and cl₁⁺/cl₁⁺) were tested for their resistance or sensitivity to erythromycin about three generations after autogamy and their growth rate was recorded. Average generation times at 27 °C are given. The erythromycin resistance or sensitivity is symbolised by + or -; ± indicates that the cells first were blocked in erythromycin and then progressively became resistant.

or for E^s mitochondria and the su condition (generation time: 7 h) according to the medium (E or N) in which they were grown.

A last point is worth consideration. This suppressor interacts not only with the product of the mutated gene *cl₁* but also with the product of the wild-type allele, *cl₁⁺*: the *cl₁⁺/cl₁⁺su* cells have a slightly increased generation time (7 h instead of 6) and a strongly decreased cytochrome oxidase content (A. S., unpublished).

In conclusion, I have identified in the *cl₁-su* strain a suppressor which behaves genetically as a mitochondrial mutation, since its transmission is linked to the mitochondrial E^s marker. The mechanism of this suppression remains to be established. It is probably not a direct informational suppression because it is very unlikely that mRNA transcribed in the nucleus is translated by mitochondrial tRNAs⁵. It is more likely an indirect suppression by functional interaction between two modified products, the one nuclear, the other mitochondrial. The identification of the product coded by this new mitochondrial mutation should provide information on the informational content of the mitochondrial DNA and on the problem of the interactions between products coded by the nuclear and mitochondrial genetic systems.

I thank Dr J. Beisson for advice and discussions.

Spontaneous AKR lymphoma with T and B-cell characteristics

THE existence of surface immunoglobulin on thymus-derived cells (T cells) has been difficult to demonstrate and is still controversial¹⁻⁶. Therefore the presence of easily detectable surface immunoglobulin (sIg) is considered to be a reliable marker for lymphoid cells of bone marrow origin (B cells)⁷. To our knowledge no cell line has been reported to bear both easily detectable sIg (that is, by immunofluorescent staining) and T-cell markers, although two murine T-cell lines have been reported to bear small amounts of sIg detectable only by extremely sensitive methods^(2,6). We now report the existence of a murine lymphoma line with both T and B-cell characteristics by the criteria of easily detectable sIg, presence of Thy1.1 (θ AKR) antigen⁸, and mitogen responsiveness.

The tumour line, designated AkTB-1, originated as a spontaneous lymphoma in the lymph nodes and spleen of a 14-month-old AKR/J mouse which had been thymectomised at 1 month of age. Lymph node (LN) cells were initially passaged, and the line was subsequently maintained *in vivo* by serial intravenous passage of 10⁵ spleen cells into young AKR/J male hosts. For comparison, cells from age-matched normal AKR/J mice or from AKR/J mice with spontaneous thymomas were studied.

Thy1.1 antigen was detected by specific immunofluorescent staining using an indirect technique. Spleen or LN cells were incubated with anti-Thy1.1 antiserum prepared by hyperimmunisation of CBA/J mice with AKR/J thymocytes. The

Table 1 Thy1.1 antigen determinations

Donor	No. of experiments	% Positive cells ± s.e.	
		Spleen	LN
Normal 3 month AKR	6	38 ± 4	71 ± 3
AkTB-1 in passage*	9	94 ± 1	91 ± 1
AKR spontaneous thymoma	3	98 ± 1	98 ± 1
AKR lymphoma in passage†	8	96 ± 4	92 ± 2

*Experiments performed after day 12 of passage.

†Cell lines derived from spontaneous AKR thymomas passaged as spleen cells. One hundred cells were counted in each experiment.

cells were washed and then counterstained with fluorescein-conjugated goat anti-mouse γ₂ heavy chain antibody. The reactivity of this anti-Thy1.1 antiserum against thymus cells could be removed completely by absorption with AKR/J brain tissue, and less than 2% of AKR/J spleen cells react with anti-γ₂ antiserum.

Lymph nodes and spleens were removed from mice on various days after passage and examined for surface Thy1.1 antigen (Table 1). By day 12, more than 90% of LN and spleen cells were Thy1.1 positive. This pattern was maintained throughout the passage. Similar results were obtained with cells from AKR mice bearing a spontaneous thymoma or another passaged AKR lymphoma cell line derived from a spontaneous AKR/J thymoma.

sIg was determined by Dickler's method¹⁰. Cells were incubated with fluorescein-conjugated goat or rabbit antibody monospecific for α, μ, γ₁, and γ₂ heavy chains, as well as with a fluorescein-conjugated polyvalent anti-mouse immunoglobulin serum. The percentage of sIg positive cells was determined at various times after passage (Fig. 1). AkTB-1 spleen cells progressively acquired sIg of the IgM class; whereas fewer than 10% of cells were sIg positive on day 14, more than 90% were positive by day 22. At all times, fewer than 5% of cells could be stained for α, γ₁ or γ₂ heavy chains (data not shown).

Fig. 1 Percentage surface immunoglobulin positive cells in LN and spleen of AkTB-1 bearing animals. Open circles represent spleen cells; closed circles, LN cells. sIg represents staining for μ heavy chain on cell surfaces. Upper bracket shows range for normal spleen cells. Lower bracket shows range for normal LN cells.

*Expressed as percentage of total spleen cells.

†Expressed as percentage of positively stained cells, see text for explanation of terms. 2×10^7 spleen cells from an AkTB-1-bearing mouse late in passage were incubated with unlabelled anti-Thy1.1 antiserum for 30 min at 4 °C, washed and then incubated with unlabelled goat anti-mouse γ_2 heavy chain antibody for 1 h at 37 °C. Either at this point or after culture overnight, cells were examined for Thy1.1 antigens (see text). For detection of sIg regeneration, a single incubation at 37 °C for 1 h with unlabelled anti-mouse immunoglobulin was performed before overnight culture. Cells were stained according to method in text.

Thus almost all AkTB-1 spleen cells late in passage bear both IgM and Thy1.1 on their surface. Few LN cells from the same animals bore sIg even late in passage when lymph nodes were grossly and microscopically replaced with tumour. Neither spleen nor LN cells from three spontaneous or two other passaged AKR lymphomas had detectable (>2%) sIg of any class.

Since the coexistence of easily detectable T and B-cell markers on the same cell is unusual, we wished to test the possibility that either Thy1.1 or sIg was passively acquired. In one experiment (Table 2), Thy1.1 on the surface of AkTB-1 spleen cells was capped by incubating the cells first with unlabelled anti-Thy1.1 serum, then with unlabelled anti-mouse γ_2 heavy chain at 37 °C¹¹. Cells stained immediately after these incubations were 100% positive for Thy1.1; in 75% the antigen was present only in the form of caps, while 25% still had a circumferential (ring) distribution of Thy1.1. After overnight incubation, cells reacted with Thy1.1 antisera and counter-stained with fluorescein-conjugated anti- γ_2 antibody all exhibited a fluorescent ring pattern. Staining with only anti- γ_2 showed 92% of cells were still capped, indicating that the Thy1.1 caps formed a day earlier had neither shed nor redistributed themselves over the cell surface. These results suggest that AkTB-1 spleen cells can generate Thy1.1 antigen.

Similar results were obtained for capping and regeneration of surface immunoglobulin (IgM) on AkTB-1 spleen cells (Table

2). In addition, preliminary studies indicate that these cells synthesise IgM *in vitro*.

Mitogen-stimulated DNA synthesis by AkTB-1 cells was determined using a microculture method. Responsiveness to phytohaemagglutinin (PHA) and lipopolysaccharide (LPS) at early, middle and late points in a typical passage are shown in Table 3. At day 7 of passage, when lymphoid organs were not yet enlarged and the frequency of Thy1.1 positive spleen cells was only slightly increased, mitogen responsiveness of AkTB-1 spleen cells was comparable with that of normal cells. By day 14, when lymphoid organs were enlarged 10-fold and spleen cells were 94% Thy1.1 positive and 33% sIg positive, spontaneous DNA synthesis was elevated, but was depressed by PHA and LPS. Late in passage when AkTB-1 spleen cells were 95% Thy1.1 and 83% sIg positive, they exhibited a high spontaneous level of DNA synthesis which was depressed by PHA but markedly stimulated by LPS. Mitogen responsiveness of AkTB-1 LN cells (Table 3) was not remarkably different from that of normal AKR cells. These results further suggest the dual nature of the spleen cells, since LPS responsiveness is considered to be characteristic of B cells¹², whereas suppression of DNA synthesis in response to PHA has been reported as a characteristic of some murine T-cell lymphoma lines^{13,14}.

AKR lymphoma usually arises in the thymus, presumably as a result of viral transformation of a susceptible cell population, and can be prevented by thymectomy¹⁵. The

*Yield indicates total number of nucleated cells in spleen or lymph nodes (inguinal, axillary and mesenteric).

†Data are mean c.p.m. \pm s.e. of triplicate cultures at the mitogen concentration resulting in optimal stimulation (PHA, $1.6 \mu\text{g ml}^{-1}$; LPS, $100 \mu\text{g ml}^{-1}$).

Cells were suspended at a concentration of 10^7 cells per ml in RPMI 1640—10% FCS with 2 mM fresh glutamine and antibiotics. 0.1 ml of cells was incubated in microtitre plates with an equal volume of medium or doubling dilutions of PHA or LPS. The cultures were incubated at 37 °C in 5% CO₂ in air for 18 h, then pulsed with $1.0 \mu\text{Ci } ^3\text{H}$ -thymidine for a further 6 h before collection.

origin of the AkTB-1 tumour line as a spontaneous lymphoma in a thymectomised mouse suggests that the absence of the thymus was important in the generation of the unusual double-marker characteristics of these cells. This hypothesis is supported by the recent appearance in our laboratory of a second sIg positive, Thy1.1 positive spontaneous tumour originating in another thymectomised AKR/J mouse. It may be that the absence of susceptible thymus cells allows the subsequent transformation of a normal double-marker cell population. Such a subpopulation has been described in man¹⁶⁻¹⁸. Alternatively the thymus may modulate neoplastic as well as normal cell differentiation, so that in its absence transformed cells develop atypical characteristics.

Regardless of the origin of these cells, the progressive acquisition of B-cell characteristics as well as their differential expression in spleen and lymph node suggest that these neoplastic cells undergo differentiation *in vivo* and that the lymphoid tissue microenvironment has a role in the control of this differentiation process.

We thank Dr Richard Asofsky and Ms Pamela Sharp for help in providing antisera and studying immunoglobulin synthesis and markers. We also thank Drs William Terry and Howard Dickler for advice and criticism.

Precommitment of normal mouse peritoneal cells by erythrocyte antigens in relation to auto-antibody production

We have reported that peritoneal cells (PCs) from unstimulated mice can, after 2 h of incubation in the appropriate medium, start to secrete anti-sheep erythrocyte (SRBC) antibodies^{1,2}. We extended this observation by showing that PCs cultured in standard conditions for 4-6 d in the absence of SRBC, can form numerous haemolytic plaques, demonstrable by the ordinary techniques of local haemolysis (in Agarose, in liquid layer or in cellulose gum³). The immunological nature of this plaque-forming activity was established by the following criteria: complement dependency, inhibition by anti-mouse IgM serum and immunological specificity. Thus, we concluded^{3,4} that PCs of normal adult mice had been stimulated previously by an unknown immunogen sharing common or cross-reacting determinants with SRBC, and that tissue culture conditions would derepress the built-in capacity of these cells to produce antibodies. Treatment of autologous erythrocytes by the proteolytic enzyme bromelain revealed that normal mouse spleen cells

regularly produce antibodies against their own erythrocytes^{5,6}. This led us to investigate the behaviour of normal PCs towards SRBC or mouse red blood cells (MRBCs) treated by bromelain (BrMRBCs). We report here that mouse PCs in culture develop a plaque-forming activity against isologous BrMRBC as well as against SRBC, and we show that these two types of erythrocytes share some common antigen.

PCs from non-immunised 22-28-week-old CBA/J or NZB mice were cultured by Mishell and Dutton's technique⁷ at a concentration of 4×10^6 ml⁻¹ in RPMI 1640 supplemented with 10% foetal calf serum. Cell viability was measured by Trypan blue exclusion. The plaque-forming activity of lymphoid cells was measured by Cunningham's liquid layer technique⁸ or the carboxymethyl cellulose technique (CMC)^{4,9}. SRBCs or MRBCs were treated with bromelain as described by Cunningham⁵. For mixed plating, an equal number (5×10^6 ml⁻¹) of BrMRBCs plus SRBCs or of BrMRBCs plus BrSRBCs was used. A mixture of equal volumes of fresh rabbit and guinea pig sera was used as a source of complement, the final concentration being 10%.

PCs from normal mice produced no plaques of haemolysis against MRBC in the liquid layer technique, and only an insignificant background was detected by day 4 of culture with the CMC technique (Table 1). On the other hand, as already described³, increasing number of plaque-forming cells (PFCs) developed against SRBCs during culture. The highly sensitive CMC technique¹⁰ provided many more plaques than the liquid technique.

If mouse erythrocytes were treated with bromelain their antigenic properties were modified so that they became sensitive to antibodies secreted by mouse PCs (Table 1). In most cases treatment of SRBCs by bromelain also led to an increase of the PFCs expressed by PCs in culture.

The behaviour of spleen cells from normal mice cultured in the absence of SRBCs was similar to that of PCs: although almost no PFCs against MRBCs and only a few background plaques against SRBCs could be detected, treatment of these erythrocytes with bromelain resulted in the appearance of a substantial number of PFCs in the spleen cell population (Table 2).

The immunological nature of the plaque-forming activity against BrMRBCs and BrSRBCs was demonstrated by the fact that no plaques appeared in the absence of complement and that 95% of PFC were inhibited by a specific anti-mouse IgM serum, added to the liquid medium or CMC at a final concentration of 1%. The system displayed immunological specificity inasmuch as horse red blood cells (HRBCs) or bromelain-treated HRBCs never gave any significant number of plaques with normal peritoneal or spleen cells (SCs). Furthermore, ghosts or SRBCs or BrMRBCs, obtained as described by Dodge *et al.*¹¹, inhibited plaques against SRBCs and BrMRBCs whereas ghosts of HRBCs did not.

As both SRBCs and BrMRBCs could be lysed by cultured peritoneal and spleen cells it was tempting to speculate that the cells share common or cross-reacting determinants. To check this hypothesis, both sorts of cells were plated with a mixture of both types of erythrocyte, and the morphology of plaques of haemolysis was examined¹². Three types of plaque were observed: (1) clear plaques, (2) 'sombrosos', where the centre was clear and the periphery cloudy and (3) incomplete or cloudy plaques. Clear plaques and sombrosos were judged as indicating cross-reactivity between antigenic determinants on the surface of both types of erythrocyte present in the gel, whereas cloudy plaques were thought to be formed in the absence of such cross reactivity. As Table 3 shows, SRBCs and BrMRBCs cross reacted slightly (10%) while BrSRBC and BrMRBC cross reacted to a large extent (40%).

These results lead us to interpret the spontaneous plaque-forming activity of PCs, and at a lower level of spleen cells, as a manifestation of an autoimmune process. As Cunningham proposed¹³, young mice would be sensitised to antigenic determinants present on their own erythrocytes but hidden in the

membrane. If these epitopes, unravelled on MRBC by bromelain, are also present in an exposed form on SRBCs, auto-antibody secreted by peritoneal and spleen cells would attach spontaneously on SRBCs.

A repressive mechanism seems to restrict the number of PFCs *in vivo* to a low level¹⁸. Our results show that, in culture conditions, their number increases considerably. Thus, the immune behaviour of PCs becomes a phenomenon of general biological importance, and perhaps an index of a spontaneous autoimmune process. Our findings underline the need for a reassessment of the concept of 'primary response' of mice to SRBCs.

Noradrenaline induces morphological alterations in nucleated and enucleated rat C6 glioma cells

GILMAN and Nirenberg¹ have reported that catecholamines induce a striking increase in intracellular cyclic AMP concentration in cultures of rat and human glioma cells. They concluded that this activation of the adenylate cyclase was mediated through the β -adrenergic receptor, since the effect was inhibited by the β -receptor blockers sotalol and dichloroisoproterenol. Another report² showed that cultured human glioma cells treated with cyclic AMP derivatives resumed the typical morphology of the normal counterparts, that is, having multiple processes extending from a compact cell body. I have therefore compared the effects of noradrenaline, a β -adrenergic stimulator, on the morphology and cyclic AMP level in rat C6 glioma cells.

I have also investigated whether the variations in cell shape require nuclear activity. The results demonstrate that the morphological alteration occurs in normal cells as well as in cells enucleated by cytochalasin B. Moreover, the effect of noradrenaline on cyclic AMP concentration and cellular morphology is transient.

In the absence of noradrenaline (Sigma) the nucleates and the enucleates have an irregular flattened shape (Fig. 1a and c, respectively). Treatment of the C6 cells and the enucleates with the drug produced a marked change in morphology; the cells and the enucleates assumed a spindle-like morphology (Fig. 1b and d, respectively). The cytoplasm retracted to form a compact cell body with multiple processes. Occasionally the treated nucleates as well as enucleates had bipolar processes. Now and then the processes showed beadings and bifurcations. Routinely, I used 10^{-5} M noradrenaline; concentrations as low as 10^{-7} M are sufficient to induce the morphological change, whereas 10^{-8} M noradrenaline has no effect.

The effects of noradrenaline on the morphology of the nucleates and the enucleates was inhibited by the β -receptor blocking agent DL-propranolol (Sigma, at 10^{-5} M), but not by phentolamine (Ciba-Geigy, 10^{-6} - 10^{-4} M), a specific α -receptor blocker.

Fig. 1 Demonstration of the morphological change in nucleated and enucleated rat C6 glioma cells caused by noradrenaline. The C6 rat glioma cells used throughout the experiment were constructed by Benda *et al.*³ and were obtained from Flow Laboratories. The cells were routinely maintained in Ham's F10 medium (Flow Laboratories, contains 0.25 mM Ca^{2+}) supplemented with 15% horse serum and 2.5% foetal bovine serum in a humidified 5% CO_2 incubator at 37 °C. In the actual experiments, the cells were allowed to recover from trypsinisation for at least 48 h in fresh medium. For the enuclea-

tion of C6 cells, the protocol described by Prescott *et al.*⁴ was followed, which in the case of C6 cells yielded more than 90% enucleation. The enucleates were then placed back in the original medium at 37 °C for 30 min to allow them to assume a normal appearance before starting the experiments. Nucleates (a) and enucleates (c) in the absence of noradrenaline and in the presence of 10^{-6} M of noradrenaline for 2 h (b and d, respectively). The cells were fixed in 100% methanol and stained with Giemsa. The micrographs were taken with Zeiss interference contrast optics. Magnification $\times 224$.

The morphological change in C6 cells, nucleates and enucleates, stimulated by noradrenaline, could be inhibited by colchicine (Serva, 1 mg ml^{-1}), added together with noradrenaline. Cells already induced by noradrenaline assumed their control appearance promptly after addition of colchicine. These observations suggest that polymerisation of the microtubules is involved in the formation of processes in C6 cells.

The morphological change in C6 cells could be observed 30 min after addition of noradrenaline (Fig. 2). At this time about 20% of the cells showed the characteristic processes. The fraction of morphologically altered cells then increased approximately linearly with time. At 4 h more than 90% of all cells

assumed the new morphology. From this time on, more and more cells looked normal once again; and 8 h after the application of noradrenaline all cells were morphologically indistinguishable from untreated cells.

In separate experiments I measured the cyclic AMP level in the cells during their morphological modulation (Fig. 2). Untreated cells had a basal level of 10 ± 4 pmol per mg protein, which is similar to that found in many tissues, including brain. But after treatment with noradrenaline the cyclic AMP concentrations increased strikingly, more than 100-fold, in agreement with previous observations by Gilman and Nirenberg¹. After 30 min the cyclic nucleotide concentration began to decrease and at 4 h it reached the 2–3-fold basal levels. The cyclic AMP level in the cells dropped to the basal value at 8 h.

The data of Fig. 2 show that most of the cells are morphologically altered when the cyclic AMP level has already dropped to almost basal levels (at 4 h). This time course indicates that both effects of noradrenaline are transient. Moreover, I have

Fig. 2 Time course of morphological alteration (bars) and cyclic AMP concentration (black circles) in nucleated C6 cells induced by 10^{-6} M noradrenaline. Parallel cultures of C6 cells grown in 6 cm dishes (Greiner) were inspected for morphological alteration. The intracellular cyclic AMP concentration was then determined in the parallel culture. Before the experiment was started, C6 cells were incubated in medium for 48 h after replating. The cells were fixed with 100% methanol and stained with Giemsa. A total of 500 cells per dish were examined for the type of morphological alterations shown in Fig. 1. For determination of cyclic AMP the medium was quickly removed by aspiration and the cells were washed twice with PBS at 37 °C and fixed with 2 ml of ice-cold 5% trichloroacetic acid. The cells were then scraped off the dish. The protein debris was removed by centrifugation and the protein concentration was determined by the method of Lowry, using bovine serum albumin (Boehringer Mannheim) as standard. The supernatant was extracted five times with ether, which was presaturated with HCl-acidified water. The samples were then freeze-dried. The dry residue was suspended in 0.2 ml of 0.2 M sodium acetate buffer, pH 4. The cyclic AMP concentration was determined according to Gilman⁵.

found that the cells did not respond to a second treatment with noradrenaline for at least 60 h. After this refractory period, noradrenaline once again induced the characteristic modulation of cyclic AMP and morphology. Addition of dibutyryl cyclic AMP (Boehringer Mannheim, 1 mM) plus theophylline (Sigma, 0.1 mM) also induced the morphological change in C6 cells.

Taken together, these results suggest that noradrenaline stimulates by way of the β -adrenergic receptor, the adenylate cyclase of C6 cells, which then acquire a morphology similar to that of the astrocytes in brain tissues. Both changes are transient and are followed by a long refractory period. There are some reports^{6,7,8} in which cyclic AMP has been implicated in tubulin polymerisation in cells, but not in a cell-free system⁹. The morphological alteration in C6 cells is prevented by colchicine, again indicating the participation of microtubules. This was directly shown for C6 cells after stimulation by noradrenaline, (Weber, personal communication) using the immunofluorescence technique for specific visualisation of cytoplasmic microtubules¹⁰.

My experiments and other reports^{7,11,12} demonstrate that the information necessary for normal cell shape and morphological change is preserved in the cytoplasm of cells enucleated by cytochalasin B. The system described here may be useful for seeking a possible causal relationship between cyclic AMP and polymerisation of microtubules.

I thank Drs R. Knippers and K. Weber for their interest in this work, Dr H. Sauer for reading the manuscript and Mr B. Schlegel for assistance. This work was supported by the Deutsche Forschungsgemeinschaft.

Genetically determined defect of Schwann cell basement membrane in dystrophic mouse

FOR more than a century there has been controversy as to whether Schwann cells are able to synthesise collagen and the collagen-related basement membrane^{1,2}. Recent evidence provides more direct proof that Schwann cells are indeed equipped to synthesise collagen and probably also a basement membrane in the same way as other cells of epithelial and neuroectodermal origin^{3–5}. Observations in various pathological situations, including regeneration after crush injury^{6,7} and in peripheral nerve ischaemia⁸ indicate that axon regrowth and Schwann cell migration occur along scaffolding consisting of basement membranes and endoneurial collagen fibres. The role of the basement membrane and the endoneurial collagen in normal myelination has, however, remained largely unknown. It has been generally accepted that these extracellular elements provide not only mechanical support

to peripheral nerves, but also that they are partly responsible for the relative lack of developmental faults in peripheral myelination⁹. A recent report¹⁰ suggests that the acquisition of a basement membrane by a Schwann cell occurs at the time that the cell establishes a permanent relationship with an axon. It is not known, however, whether the association of the axon with the Schwann cell induces the latter to synthesise basement membrane, or whether the Schwann cell only establishes a relationship with an axon once the Schwann cell has acquired a basement membrane.

There are at least three ways of investigating this problem: (1) by making serial observations during embryogenesis; (2) by studying the effects of selective damage to basement membrane and collagenous elements on myelination; or (3) by studying the mutant dystrophic mouse, in which areas of apparent early arrest of Schwann cell development and myelinogenesis are known to occur, particularly in the proximal peripheral nervous system^{11–13}. Our observations on the dystrophic mouse indicate that a genetically determined partial deficiency of basement membrane is present in the Schwann cells of the peripheral nervous system, and suggest that the Schwann cells develop basement membrane before establishing a definitive relationship with the axons.

Dystrophic (*dy/dy*) mice of 1, 2, 3 and 5 months of age were studied. Phenotypically normal littermates of the dystrophic animals (+/?) and C57BL mice were used as controls for each age group. They were prepared for electron microscopy as reported previously¹¹. Segments of the sciatic nerve 4–5 mm above the sciatic notch were studied at all time points, and at 3 months of age the common peroneal nerve was also examined.

A consistent finding in all dystrophic mice was a patchy deficiency of the basement membrane of Schwann cells of fibres which were myelinated (Fig. 1). The basement membrane was completely absent in amyelinated zones. In longitudinal sections, myelinated fibres entering an area of amyelination lost not only their Schwann cell covering and myelin sheath, but also the associated patchy basement membrane (Fig. 2). Some of the myelinated fibres had abnormally long bare nodal segments, without the usual basement membrane and Schwann cell pseudopodial covering. The abnormally long bare nodes are probably responsible for the 25% reduction in the sciatic nerve conduction velocity found by Huizar *et al.*¹⁴. Skin basal cells, skeletal muscle fibres, and endoneurial blood vessels showed continuous basement membrane of normal thickness. The basement membrane of the normal littermates (+/?) was normal, and identical to that in the normal C57BL mice. The defect of basement membrane was thus inherited in an autosomal recessive manner in these dystrophic mice, and presumably the gene responsible for the dystrophy is also responsible for the basement membrane defect.

Peripheral nerve development in the normal foetus involves migration of Schwann cells around bundles of axons, the progressive division of these bundles into smaller and smaller groups by proliferating Schwann cells, and the eventual segregation and enwrapping of axons by Schwann cells^{15–17}. The exact final relationship depends on whether the axon is to become a myelinated or an unmyelinated fibre. The observations of Webster and colleagues¹⁰ on tadpole nerve indicate that migrating Schwann cells lack basement membrane, which only forms when the Schwann cell establishes a permanent relationship with an axon. In mammalian foetal nerve the Schwann cells taking part in the segregation of axon bundles already have basement membranes^{18,19}. Our studies of the mutant dystrophic mouse show that Schwann cell basement membrane is patchily deficient throughout the peripheral nervous system, and that uncommitted (presumably Schwann) cells around amyelinated nerve fibre bundles in the nerve roots have a similar, and sometimes more marked, deficiency of basement membranes. This basement membrane deficiency is probably the result of impaired Schwann cell function, rather than of an inadequate axonal signal to the Schwann cell. The basement membrane deficiency in the

Fig. 1 Two-month-old mouse upper sciatic nerve showing portions of 3 myelinated nerve fibres. *a*, Normal C57BL; *b*, *dy/dy* mouse. In *a* the basement membrane over the Schwann cells is complete, and the minimum separation of 2 Schwann cell plasma membranes is 78 nm. In *b* the dystrophic basement membrane is patchy and incomplete, which allows the plasma membranes of two Schwann cells to approach to within 55 nm in this figure (middle). In some instances, dystrophic Schwann cells plasma membrane approached close enough to form an intraperiod line. In *b* there is apparently abnormally wide separation of the leaflets of the Schwann cell plasma membrane. $\times 45,000$.

dystrophic mouse may therefore simply represent a deficiency of Schwann cell function; there is already suggestive evidence of other Schwann cell abnormalities including an oligodendroglial-like arrangement of some Schwann cells (E. J., R. M.

and W. G. B., unpublished), and of aberrant axonal enwrapment and myelination¹¹.

It is possible to advance an hypothesis relating the peripheral nervous system abnormalities to the basement membrane deficiency. Let us suppose that synthesis of the basement membrane were necessary to terminate Schwann cell migration, and to establish a permanent relationship between the Schwann cell and an axon. The decreased ability to synthesise basement membrane characteristics of the dystrophic mutant Schwann cell would result in a greater tendency for Schwann cells to migrate further from the neural crest. Fewer Schwann cells would therefore come to rest in the spinal roots, and those which did settle, both in the roots and more peripheral parts of the nervous system, would show a decreased capacity for axonal enwrapment and myelinogenesis.

There are, however, still some features of the dystrophic mouse peripheral nervous system which are not fully explained by this hypothesis. These include the exact distribution of the neural abnormality, the presence of uncommitted Schwann cells around myelinated axons, and the aberrant myelination in the spinal roots^{11,12}.

To the best of our knowledge this is the first reported incidence of a genetically determined deficiency of basement membrane production of Schwann cells, though abnormalities of the basement membrane have been incriminated in other diseases. In Alport's syndrome (hereditary nephropathy with nerve deafness), the basement membrane of renal glomeruli shows focal thickening, thinning and splitting, and this abnormality is genetically determined²⁰. Deficiency of epithelial basement membrane is believed to be of importance in the invasiveness of carcinoma^{21,23}, and has also been reported in dermatitis herpetiformis²⁴. The Schwann cell of the mutant dystrophic mouse may therefore prove to be an equally useful

Fig. 2 Two-month-old *dy/dy* mouse upper sciatic nerve showing an axon in longitudinal section. To the left is a paranodal termination of the Schwann cell cytoplasm and its myelin sheath. In the middle and right, the axon is naked with neither Schwann cell nor basement membrane covering. $\times 4,500$.

tool to those interested in basement membranes, peripheral nerve development and oncology.

Mosaicism in organisation of concanavalin A receptors on surface membrane of mouse egg

PLANT lectins have proved to be useful probes of the surface properties of a variety of cells and membranes, providing data on the relative mobility of intramembranous macromolecules in different conditions¹ and on the organisation of oligosaccharides on the cell surface. We report here the use of fluorescent concanavalin A (con A) as a probe to analyse the surface properties of the unfertilised and fertilised mouse egg. Similar experiments were carried out independently at both Cambridge and Birmingham and the results are combined.

The fluorescent staining pattern (for details, see Fig. 1) of unfertilised eggs was not uniform. An area of weak or absent staining, designated the 'negative area', was consistently detected, occupied approximately one-fifth of the egg's surface and was associated in some but not all eggs with a slight distension of the cytoplasmic membrane (Figs 1a and 2). Cytological investigation and vital staining with acridine orange revealed that the negative area was consistently associated with the underlying second metaphase spindle. After incubation at 20 or 37 °C the negative area was separated from positively stained membrane by a sharply defined boundary line (Fig. 1b), but the boundary appeared more diffuse after incubation at 4 °C. The higher temperatures also affected the pattern of staining within the positive area converting it from a dullish even fluorescent staining to a bright patchy staining pattern at concentrations of con A in excess of 50 µg ml⁻¹ (Fig. 1c).

Various drugs were examined for their effects on the staining pattern. Preincubation in neuraminidase (50 or 100 IU ml⁻¹, Behringwerke) did not affect the staining pattern. Sodium azide at 0.5 × 10⁻² M tended to exaggerate the punctate staining of the positive area and caused the area

of negative stain to contract in size (Fig. 1c) and in many eggs to disappear altogether (Fig. 1d). The progressive loss of negatively staining membrane was often accompanied by a breakdown in sharpness of the interface between the two areas. Essentially identical results were obtained with 1, 10 or 100 µg ml⁻¹ cytochalasin B. Dimethylsulphoxide (DMSO) at equivalent dilution to that used to dissolve the cytochalasin B had no effect. The effect produced by both azide and cytochalasin B was observed at whatever stage in the protocol the drug was added, but was more marked if the drug was added before and during incubation with con A than if added after incubation. The effect was partially reversible, removal of cytochalasin B leading to an increased incidence of larger negative areas amongst eggs. Colcemid at doses from 0.36-36.00 µg ml⁻¹ had no effect on the staining pattern. Colcemid, cytochalasin B, DMSO and azide all caused rounding up of the eggs to spherical shapes, and cytochalasin B and DMSO, but not azide, caused a slight displacement of the metaphase spindle away from the surface membrane.

Newly fertilised eggs at pronuclear stages and earlier were also examined for reaction with con A. The egg was positive over the whole membrane, displaying a patchy staining pattern when incubated at 20 or 37 °C. The patchy, as distinct from smooth, staining pattern on fertilised eggs was induced by concentrations of con A one-fourth the minimum dilution effective for unfertilised eggs. An association was noted between a patchy staining pattern and the agglutination of eggs by con A, as both occurred more with fertilised than unfertilised eggs, with azide or cytochalasin B present and at 37 but not at 4 °C. The membrane overlying the midbody connecting the egg to the polar body was intensely positive, but the polar body was always either negative or had a small cup-shaped region of positive stain at its junction with the midbody (Figs 1e and 2).

These experiments demonstrate that the plasma membrane of the unfertilised mouse egg seems to be a mosaic of two distinct regions, one staining with fluorescent con A and constituting most of the egg's surface, the other on which little or no stain is detectable, overlying the second metaphase spindle and specifically isolated as the membrane of the second polar body. This pattern is susceptible to disorganisation by azide, which inhibits energy-dependent processes, and by cytochalasin B, which affects surface membrane activity and microfilament organisation. As it seems probable that energy-dependent microfilament activity is in part responsible for organising the contractile ring of the cleavage furrow which partitions the cell at division³, the mosaicism in the organisation of the surface con A-binding groups may reflect an underlying intracellular organisation dependent on microfilaments.

The nature of the membrane mosaicism is not clear from these experiments but could exist at either a structural or molecular level. A mosaicism of the underlying intracellular organelles is well established from ultrastructural studies, which have shown the cytoplasm in the spindle region to be relatively devoid of cortical granules, multivesicular bodies and membrane laminae². The mosaicism of con A binding seen at the light microscope level may be a molecular correlate of this polarity. The staining seems to be a genuine surface phenomenon and not the result of a selective pinocytosis in the positive area, as preincubation in azide and cytochalasin B caused extension of staining over the whole area rather than loss or reduction of positive staining. Organisation of the membrane of the positive area into microvilli may increase the fluorescence intensity either by increasing the effective density of con A-binding sites through corrugation of the surface or by effecting a reorganisation of binding sites within the membrane itself⁴. The intense staining of the midbody region is most probably caused by extensive surface corrugation²,

Fig. 1 Fertilised and unfertilised eggs were recovered from outbred CFLP and LACA mice within 2–3 h of superovulation. The cumulus cells were removed with hyaluronidase (Koch-Light 50 IU ml⁻¹ in phosphate-buffered saline with 10% polyvinylpyrrolidone), and the zona pellucida was removed with Pronase (0.5%, Tris-citrate buffer pH 7.0). Eggs were washed in medium PB1 (ref. 5) and used immediately. Eggs (5–10) were placed under oil in each well of a microtitre dish (Baird and Tatlock, tissue-typing slide catalogue 77 403/0522). Reagents were added by washing the eggs in each well with three changes of PB1 + reagent. Incubations were carried out at 4, 20 or 37 °C for 20–30 min. After incubation the eggs were washed in several changes of medium. A coverslip was applied and the eggs viewed on a Zeiss Photomicroscope (light source HBO200; excitation filters KP490 and 500, and LP455; barrier filters KP560 and LP520). Photographs were taken using Kodak recording film 2475. Fluorescein-labelled con A was obtained from Miles Laboratories and also synthesised in the laboratory. The activity was titrated and a final concentration of 50 µg ml⁻¹ was used in most experiments. α -Methyl-D-mannoside blocked staining. *a*, Unfertilised mouse egg incubated with fluorescein-labelled con A (25 µg ml⁻¹) at 20 °C for 30 min. Note absence of staining at one pole of egg ($\times 264$). *b*, As *a* but at lower magnification to show the clearly defined line of demarcation separating positive and negative areas ($\times 80$). *c*, Unfertilised egg stained with fluorescein-labelled con A in the presence of azide. Note how the size of the negative patch has contracted ($\times 80$). *d*, As *c* but showing an egg in which no negative area is visible ($\times 80$). *e*, Fertilised egg showing positive stain over whole surface of egg, intense stain of midbody but absence of stain in adjacent polar body ($\times 264$).

Fig. 2 Diagram indicating organisation of unfertilised (*a*) and fertilised eggs (*b*). Dotted outline indicates region of negative area.

and in preliminary ultrastructural studies we have found a reduced incidence of microvilli over the metaphase spindle. These aspects are being explored further at the ultrastructural level using ferritin-labelled con A.

Mosaicism at a molecular level could arise for several reasons. Masking of con A-binding residues in the negative area by neuraminidase-sensitive material has been excluded experimentally. Mannose-bearing oligosaccharides could be selectively excluded from the negative area. Alternatively, the oligosaccharides could be present but immobilised perhaps by way of microfilaments in such a way as to prevent cross linking by con A and their visualisation in patches¹, as evidently occurs elsewhere on the membrane. Note that in these studies the zonae pellucidae were removed by Pronase, which could have effects on the susceptibility to patching of the egg membrane.

Whatever the basis of the mosaicism, con A promises to be a useful probe of surface properties of the egg in different conditions. Such observations may also be relevant to the mechanisms of sperm-egg interaction. We have observed that sperm attachment *in vitro* to the negatively staining areas of zona-free unfertilised eggs is rare (M.H.J., and D.E., unpublished). The mosaicism of con A receptors may reflect an underlying membrane organisation, pre-

venting sperm attachment and fusion at a site at which extrusion of the second polar body may be impaired or abnormal extrusion of the fertilising sperm head may occur. Haploid or triploid states might thereby be avoided.

Release of immunoreactive luteinising hormone-releasing hormone and thyrotrophin-releasing hormone from hypothalamic synaptosomes

THE hypophysiotropic hypothalamus regulates the secretion of the anterior pituitary gland through the production and release of specific peptide hormones. Luteinising hormone-releasing hormone (LHRH) and thyrotrophin-releasing hormone (TRH) are two such peptides which have been fully characterised and synthesised^{1,2}. Studies on intact animals have revealed the importance of various neurotransmitters and hormones in the modulation of hypothalamic LHRH and TRH secretion but little is known of the cellular mechanisms involved in such control, especially at the neurosecretory nerve terminal. We have described^{3,4} the use of nerve endings (synaptosomes) isolated from the mammalian hypothalamus to investigate factors which influence the release of corticotrophin-releasing factor (CRF). As this factor is uncharacterised, a major limitation of this work has been the use of bioassay techniques to measure indirectly corticotrophin-releasing activity. In the study described here radioimmunoassays have been used to measure the release of immunoreactive LHRH and TRH from synaptosomes prepared from rat and sheep hypothalami, and we report the influence of neurotransmitters and steroid hormones on these processes.

Nerve endings were isolated from hypothalami (600–800 mg, wet weight, sheep; 30–50 mg, rat) by the method described previously⁴ and suspended in Krebs bicarbonate medium containing 10 mM glucose at a concentration of 1 and 3 hypothalamic equivalents per ml for sheep and rat, respectively. In some experiments sheep hypothalami were dissected into three regions: the median eminence (50–100 mg); a more dorsal, medial periventricular region (250–300 mg) and the remainder of the hypothalamus. These fragments were collected and treated separately. Samples (1 ml) of synaptosome suspensions were incubated for 30 min at 37 °C in capped glass vials. Electrical field stimulation was carried out during the last 20 min of incubation by passing alternating square wave pulses through concentric gold ring electrodes immersed in the synaptosome suspensions. The parameters of this electrical stimulation have been described previously⁴. Potassium stimulation was achieved by increasing the potassium concentration of the incubation medium to 60 mM during the last 10 min of incubation. In further experiments neurotransmitters or steroid hormones were added directly to the vials in 20 µl of incubation medium. After incubation the synaptosomes were removed by centrifugation, and the supernatants were rapidly frozen immediately and stored at –20 °C for 1–5 d before measurement of the LHRH and TRH content by radioimmunoassays, which have been described in detail elsewhere^{5,6}.

Synaptosomes isolated from whole sheep hypothalami released both LHRH and TRH to the medium (Table 1). Unstimulated preparations released almost fifteen times more TRH than LHRH, estimated on a molar basis, whereas electrical stimulation produced a sevenfold increase in LHRH and a fivefold increase in TRH in the medium. In contrast, depolarising concentrations of potassium had no significant effect on the release of either hormone. This difference in response to the two stimuli is surprising: it is possible either that the transitory depolarisations produced by electrical pulses are a more effective stimulus than the tonic depolarisation produced by potassium, or alternatively that elevated potassium levels may in some way stimulate the reuptake or degradation of the

Table 1 Release of immunoreactive LHRH and TRH by synaptosomes isolated from sheep hypothalami

Test	LHRH	TRH
Control	271 ± 24 (11)	1,536 ± 182 (14)
60 mM K ⁺	289 ± 23 (12)	1,617 ± 148 (9)
Electrical field stimulation	2,018 ± 696 (12)*	7,217 ± 1,060 (12)†

hormones released to the medium. Synaptosomes prepared from whole hypothalami of sheep were incubated in the presence of a range of concentrations of neurotransmitters known to be present in the mammalian hypothalamus, particularly in the median eminence (Table 2). Dopamine at concentrations of 10⁻¹⁰ M or more stimulated the release of LHRH but was without effect on TRH release. In contrast, 5-hydroxytryptamine (5-HT) at 10⁻⁸ M had no effect on LHRH release but significantly inhibited the release of TRH. Acetylcholine, noradrenaline and adrenaline were without effect on either LHRH or TRH release.

Nerve endings prepared from the three dissected regions of the sheep hypothalamus were also incubated and electrically stimulated or tested with dopamine (10⁻⁸ M) and the results are shown in Table 3. The levels of LHRH and TRH released from control and electrically stimulated preparations from the median eminence resembled those obtained with preparations derived from whole hypothalamus. The incubation of median eminence synaptosomes in the presence of dopamine stimulated the release of both LHRH and TRH. The absence of an effect of dopamine on TRH release in preparations from the whole hypothalamus may thus reflect the heterogeneous nature of the synaptosome population and the possibility that inhibitory neurotransmitters or other factors can block the stimulation induced by dopamine.

Synaptosomes prepared from the central periventricular region and the remainder of the hypothalamus released low

Values represent pg of immunoreactive hormone (mean ± s.e.m., number of experiments in parentheses) released to 1 ml of a suspension of hypothalamic synaptosomes (equivalent to one hypothalamus) prepared from three different regions as described in the text and incubated for 30 min in Krebs bicarbonate medium at 37 °C. Electrical stimulation was carried out during the last 20 min of incubation while dopamine was added at the start of the incubation period: Student's *t* test: **P* < 0.001, †*P* < 0.005, ‡*P* < 0.02, §*P* < 0.05—tested against control results for each preparation.

levels of LHRH whereas the amounts of TRH were higher and comparable with those released from median eminence preparations. Electrical stimulation caused release of both hormones and the responses were of similar magnitude to those obtained with synaptosomes prepared from the median eminence. In contrast with the latter preparation, dopamine added to synaptosomes obtained from the periventricular region or remainder of the hypothalamus did not result in the increased release of LHRH or TRH. This may indicate that the LHRH and TRH-containing nerve endings which terminate outside the median eminence do not possess receptors for dopamine, or that these preparations contain an inhibitory factor(s) which may block the response to this transmitter.

The inhibitory effect of 5-HT on TRH release and the stimulatory effect of dopamine on LHRH and TRH release from synaptosomes prepared from the median eminence are consistent with findings obtained in the whole animal^{7,8}, and with the isolated hypophysiotropic hypothalamus incubated *in vitro*⁹⁻¹¹. These results, together with our finding³ that acetylcholine stimulates and dopamine inhibits the release of CRF from hypothalamic nerve endings, suggest that the neurotransmitters present in the median eminence have a specific role in modulating the release of hypophysiotropic hormones. The extent and physiological significance of such control mechanisms at the neurosecretory nerve terminal remain to be established but further evidence for integration at this level has been obtained from experiments in which the effects of gonadal steroids on the release of LHRH from synaptosomes prepared from the rat hypothalamus have been investigated.

Adult female Sprague-Dawley rats (250 g body wt) were treated with 17- β -oestradiol and progesterone, alone and in combination, administered as a microparticulate suspension in the drinking water (10 μ g ml⁻¹) for 20 h (average ingested dose 150 μ g per rat) before killing, removal of the hypothalamus and preparation of synaptosomes. The same steroids were tested *in vitro* at a concentration of 10⁻⁸ M for a direct

action on hypothalamic synaptosomes prepared from untreated rats. In all cases tested the release of TRH was unaffected by these procedures. Table 4 shows that synaptosomes prepared from the rat hypothalamus released much smaller amounts of LHRH than the sheep preparations (14 pg per hypothalamic equivalent compared with 271 pg) although these amounts are in proportion to the weights of original tissue. Pretreatment with oestradiol or progesterone *in vivo* resulted in a two- to threefold increased release of LHRH, whereas simultaneous pretreatment with both hormones produced a marked inhibition. When added directly *in vitro*, oestradiol (10⁻⁸ M) alone had no apparent effect on the nerve endings, although progesterone (10⁻⁸ M) alone and in the presence of oestradiol resulted in an increased release of LHRH. The rats used in these experiments were mature females in all stages of the oestrous cycle and the results can only confirm the complexity of interactions between gonadal steroids and the synthesis and release of LHRH. The *in vitro* results, however, suggest that at least part of the feedback effects of gonadal steroids may occur at the neurosecretory nerve ending; an effect analogous to our previous finding³ that glucocorticoids inhibit the release of CRF from hypothalamic synaptosomes. To clarify further the effects of gonadal steroids *in vitro* shown in Table 4, the effects of 17- β -oestradiol and progesterone on the basal release of LHRH from hypothalamic synaptosomes prepared from female rats taken from specific stages of the oestrous cycle are now being examined. Like the actions of neurotransmitters, the effects of gonadal steroids administered *in vitro* seem to be specific. Thus progesterone increases the release of LHRH, but has no effect on TRH release and at high levels inhibits the release of CRF induced by electrical stimulation. These findings support our view³ that steroids may influence neural processes through mechanisms which do not involve the classical nuclear receptor for such hormones. Studies are in progress to establish whether these effects could be mediated through the action of cyclic nucleotides and mechanisms involving protein synthesis.

This work was supported through an MRC programme grant to J.A.E. We thank Mrs J. Pennington for technical assistance.

Isolation and structure of urogastrone and its relationship to epidermal growth factor

THE clinical observation of the very low incidence of peptic ulceration during pregnancy led to the finding that extracts of the urine of pregnant women had a beneficial effect on experimental ulcers in dogs¹. It was later reported that not only pregnancy urine but also that from all females and males contained a potent inhibitor of gastric acid secretion^{2,3}. Sandweiss⁴ named the anti-ulcer factor anthelone and regarded it as having a therapeutic effect on ulcers without depressing gastric acid secretion. The antisecretory agent was thought to be a separate entity and was called urogastrone because its actions resembled those of the postulated duodenal hormone enterogastrone⁵. Subsequent work amply demonstrated urogastrone action, but the existence of anthelone as a separate entity remained less well established. To establish the true nature of these agents, however, and in particular their possible role in the therapeutic control of peptic ulceration it was necessary to make a full chemical identification. Many attempts have been made to isolate urogastrone, and probably the most highly purified sample on record was that obtained by Gregory⁶. This was described as a combination of a golden yellow fluorescent pigment and a protein of relatively low molecular weight. Others have provided additional evidence of a protein structure⁷ but some recent work has led to the suggestion that urogastrone is a high-molecular weight glycoprotein^{8,9}. Nevertheless its exact nature, source¹⁰ and physiological role have remained unknown. Gastric inhibitory effects have also been shown by extracts of animal urine but studies were undertaken on the nature of urogastrone from more readily available human urine.

Highly purified samples of urogastrone from normal male urine have now been obtained by means of a twelve-stage purification process involving ion exchange, partition and gel chromatography¹¹. There seems to be more than one inhibitor of gastric acid secretion in urine but the main active components were eventually obtained in yields of less than 1 mg per 1,000 l of urine. Two closely related products were isolated and for these the original name of urogastrone has been used. The two urogastrones were shown to be water-soluble polypeptides of relatively low molecular weight and the difference between them could be shown by various physical techniques including acrylamide gel electrophoresis (Fig. 1). They caused an intense inhibition of gastric acid secretion in cats and dogs (when tested as described¹² for less pure material obtained previously) and seemed to be biologically indistinguishable. Because of the small amounts of material available, the two peptides were sometimes used together. Doses as low as 0.25 µg kg⁻¹ produced 60–80% inhibition in Heidenhain pouch dogs stimulated to near maximal levels of acid secretion with pentagastrin or histamine. Work with less pure material had established that at doses producing strong inhibition of acid secretion, urogastrone did not affect other secretions such as pancreatic, biliary or salivary secretion and the effects seemed to be quite specific for the stomach. It did not affect blood pressure, pulse rate or body temperature¹³. Also, it did not seem to be inhibiting acid secretion by causing restriction of mucosal blood flow^{13,14}. Urogastrone has been shown to be active in a number of species and, in man, doses of 0.25 µg kg⁻¹ strongly inhibit gastric secretion induced by different stimuli¹⁵. Acid secretion was also

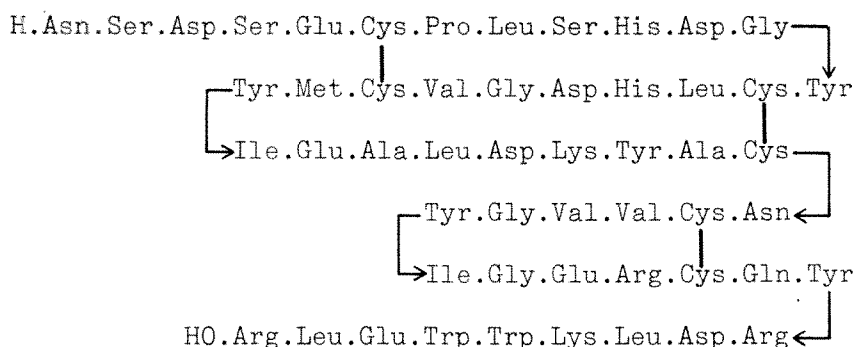

Fig. 1 Thin-layer acrylamide gel electrophoresis at pH 8.9 in which the two urogastrones (β -Ug, γ -Ug) and epidermal growth factor (EGF) are compared with control samples of bovine insulin (INS) and bovine serum albumin (BSA) stained with amido black. The lower edge of the photograph indicates the origin and the upper edge the distance moved by bromophenol blue to the anode.

reduced in patients with Zollinger Ellison syndrome who had massive gastric hypersecretion¹⁶.

The two isolated polypeptides, designated β and γ urogastrone, were found to consist of 53 and 52 amino acid residues respectively. The full structures of these peptides have now been established (Fig. 2) and it was found that the difference resided only in the C-terminal arginine residue which was absent in the γ peptide (H. G., and B. Preston, unpublished). The amino acid sequence was established mainly by degradation of the S-carboxymethylated or S-carboxamidomethylated peptides using trypsin, chymotrypsin, thermolysin or partial acid hydrolysis followed by dansyl Edman degradation of the isolated fragments. The protease derived from *Armillaria mellea* was of particular value, giving specific bond cleavage on the amino side of lysine^{17,18} and providing three fragments from urogastrone derivatives. The positions of the disulphide bonds were established by partial acid degradation of the intact urogastrone molecule.

When this sequence was established it seemed to be quite different from any other known structure and from known gastrointestinal hormones in particular. But a structure has recently been presented for mouse epidermal growth factor (EGF)¹⁹, a polypeptide isolated from the submaxillary glands of male mice which seem to be quite a rich source of biologically active peptides. Early work with this material showed that it possessed the remarkable property of causing premature eye opening when injected daily into newborn mice²⁰ and it has subsequently been shown to stimulate the growth of epithelial cell tissue in a variety of preparations²¹. EGF was isolated as 53 and 51 residue peptides and the published structures showed interesting similarities to urogastrone. Epidermal growth factor was therefore isolated by Cohen's procedure with minor variations and the material obtained had physical properties as described²². The behaviour of EGF on thin-layer acrylamide gel

Fig. 2 The amino acid sequence of β -urogastrone.

electrophoresis was compared with the two urogastrones (Fig. 1); it moves more slowly to the anode at pH 8.9 than the two urogastrones which differ by the single arginine residue. The potency of this preparation was confirmed by its action on newborn mice (Alderley Park Strain). EGF given as subcutaneous injections of 5 μ g in 25 μ l saline d^{-1} caused the eyes to open on day 10 compared with day 13 in the controls²³. It was found subsequently that this material would produce strong inhibition of gastric acid secretion in rats and dogs when given intravenously against exogenous stimuli²³. But the doses of EGF required to induce eye opening ranged from over 300 μ g $kg^{-1} d^{-1}$ initially to about 100 μ g kg^{-1} , whereas inhibition of acid secretion was obtained with less than 0.5 μ g kg^{-1} in dogs and less than 10 μ g kg^{-1} in rats. The time course of inhibition was indistinguishable from that obtained by intravenous injections of urogastrone¹². Maximum inhibition was obtained 15–30 min after injection and secretion then gradually returned to plateau levels after some 90 min. Longer periods of inhibition could be obtained by giving the peptides subcutaneously at rather higher doses. It seemed, therefore, that EGF had biological actions similar to those established for urogastrone and so urogastrone was examined to see whether it would produce the known effects of EGF on newborn mice. At the established dose levels of 5 μ g per mouse d^{-1} it was found that urogastrone would also induce eye opening on day 10 compared with day 13 for the controls (J. M. Bower, unpublished). Although the full spectrum of EGF actions has not been studied there is substantial overlap in the properties of the two polypeptides.

The two peptides show remarkable structural similarities

(Fig. 3). Of the 53 amino acid residues comprising the longer urogastrone and EGF molecules 37 are common to both peptides. The six cysteines occupy the same relative positions and the three disulphide bonds are formed in the same direction. The 16 variable residues occur at intervals along the chains and of these, 14 are interpretable as single base changes in the coding triplets. The two additional pairs are at position 28—Ser, Lys—and position 44—Thr, Tyr. The longest sequences common to both peptides consist of five residues but one of these—the interesting looking C-terminal pentapeptide—does not seem to be necessary for inhibitory activity^{24,25}.

The overall number of changes is perhaps greater than found typically in hormones with similar functions from different species²⁶. There are only four changes in the 51 residues of the insulins of mice and men although guinea pig insulin shows 16 changes when compared with that of man. On the other hand, there are hormone families, the gastrointestinal group of secretin, glucagon, VIP and GIP for example, in which differing biological actions are associated with molecules having common structural features. In this case, secretin differs from glucagon by 14 of the 29 residues²⁷. The structural relationship of urogastrone and epidermal growth factor, however, is supported by apparently identical biological actions.

The salivary glands of species other than the mouse are not a good source of the growth factor²⁰ and only the male mouse provides substantial quantities. Females can be made to produce much larger amounts of EGF, however, as a result of androgen treatment²⁸. This sexual dimorphism does not normally apply to urogastrone and levels in urine are very similar for the human male and non-pregnant female¹⁰. Interestingly, the only

indications of differences in urogastrone excretion lie in the many reports of higher urinary levels during pregnancy, when oestrogen and progesterone levels are raised. A recent study with a mouse EGF immunoassay showed that blood levels of an immunoreactive species could be demonstrated during the early stages of pregnancy in humans but none could be detected in the male or non-pregnant female²⁹. A sensitive radioimmunoassay for human urogastrone as well as EGF has been developed (H. G., J. E. Holmes, and I. R. Willshire, unpublished) and accurate determinations of urogastrone and possible EGF in various human conditions are being made.

Recently, a human epidermal growth factor has been isolated from human pregnancy urine and a total amino acid composition has been given³⁰. These figures are given in Table 1 together with mouse EGF and are compared with the ratios for β -urogastrone. Although there are differences in several of the figures, those for human EGF are not far removed from the urogastrone ratios and may be indicative of two closely related polypeptides. Because the problems of obtaining accurate amino acid ratios with small amounts of material are well known, however, it is probable that urogastrone and human epidermal growth factor are one and the same.

It is worth recalling the definition that Sandweiss applied to anthelone over 30 years ago—that it produced a beneficial effect on experimental ulcers by promoting fibroblastic proliferation and epithelialisation of the mucosa³¹. It seems that the gastric inhibitory polypeptide urogastrone may also have the epithelial growth characteristics once ascribed to anthelone as a separate entity and work now in progress will show whether it may be of value as a therapeutic agent in the treatment of duodenal ulceration.

I thank colleagues who have been involved in different aspects of the work on urogastrone and in particular Mr I. Willshire, Mrs B. Preston, Dr J. Raventos, Mrs E. Haworth, Dr L. Gerring, Miss J. Bower and Mr W. Broadbent.

Incorporation of GMP into specific tRNA molecules by extracts of Ehrlich ascites tumour cells

ENZYMATIC activities for synthesising four ribohomopolymers, including poly(G), have been found in rat liver, and all are stimulated by RNA^{1,2}. Recently two poly(G) polymerases were isolated from plant cells; one requires poly(G) as a primer³ and the other denatured DNA⁴. We report here the isolation of an enzyme from Ehrlich ascites tumour, which catalyses the incorporation of GMP from GTP into an acid-insoluble product. This enzyme requires specific tRNAs as primers. Our data suggest that the tRNAs which can serve as primers are specific to tumours or tissues infected with tumour viruses.

The GTP incorporating enzyme activity we studied was

Fig. 1 Primer activity of various tRNAs from Ehrlich ascites tumour. About 3.8 ml of tRNA solution (2.4 mg ml⁻¹) containing 0.25 M NaCl was applied to a 0.6 × 90-cm RPC-5 column, previously equilibrated with buffer (0.01 M Tris-HCl, pH 7.5, 0.01 M Mg(CH₃COO)₂, 0.0003 M 2-mercaptoethanol, 0.4 M NaCl). A 400-ml linear gradient of 0.5–1.0 M NaCl was generated and pumped (about ~20 kg cm⁻²) through the column at about 0.3 ml min⁻¹. 4.7-ml fractions were collected. This experiment was performed at the National Cancer Center Research Institute, through the kindness of Dr S. Nishimura. The absorbance at 260 nm of each fraction was measured (dotted line). Primer activity of each fraction was measured by adding 0.02 ml of each fraction into the standard reaction mixture containing 30 µg of enzyme protein (continuous line).

The standard reaction mixture contained in a total volume of 0.25 ml, 22 μmol of Tris-HCl, pH 8.0, 3.2 μmol of MgCl₂, 0.02 μmol of 2-mercaptoethanol, 0.1 μmol of ³H-GTP (2 × 10⁶ c.p.m. per 0.1 μmol). 30 μg (experiment 1) or 25 μg (experiment 2) of enzyme protein and each of the indicated RNAs as a primer were added. After incubation at 36 °C for 20 min, the cold 5% trichloroacetic acid-insoluble materials were collected on membrane filters, and the radioactivity of the dried filters was counted. Male mice (ddY) were inoculated intraperitoneally with 10⁶ cells per mouse of Ehrlich ascites tumour cells, supplied by Dr D. Mizuno (Tokyo University), and after 6 to 8 d, cells were collected and used for preparation of enzyme and RNA. RNAs were extracted from *E. coli* cells, Ehrlich ascites tumour cells, and tissues of mouse and rat by cold sodium dodecyl sulphate-phenol methods¹⁰. tRNA and rRNA fractions were prepared by 5–30% glycerol gradient centrifugation of whole RNA. Ten purified *E. coli* tRNAs were supplied by Dr S. Nishimura (National Cancer Center Research Institute). Qβ phage RNA was prepared as described by Haruna and Spiegelman¹¹. Other phage RNAs were gifts of Dr T. Shiba (Mitsubishi-Kasei Institute of Life Science). TMV RNA was given by Dr Y. Okada (Tokyo University).

found in the RNA-dependent RNA polymerase fraction⁵ of Ehrlich ascites tumour cells, and we have further purified the enzyme about 30-fold (see legend to Table 2). The whole RNA fraction extracted from these cells was active as a primer (Table 1). When the whole RNA was fractionated, tRNA was about four times as active as the whole RNA, while rRNA was almost inactive. To determine whether all the molecular species of tRNA were active as primers the tRNA fraction of Ehrlich ascites tumour cells was further separated by a reversed-phase chromatography, RPC-5 (ref. 6). Figure 1 shows clearly that some specific tRNAs were quite active as primers and others were inactive. The primer activity of tRNA in the fraction 35 of Fig. 1 was seven times that of unfractionated tRNA. Further separation of the tRNAs and ultimately the sequence analysis of each purified species will be necessary to identify the molecular species of the tRNAs which are active as primers.

To obtain information about the common structural characteristics of the primer tRNAs, we tested the primer activity of various RNAs extracted from *Escherichia coli* (Table 1), since the complete nucleotide sequences of about ten *E. coli* tRNAs have been determined^{7,8}. The whole RNA extracted from *E. coli* was active, and tRNA was also quite active but rRNA was almost inactive. Among the ten purified tRNAs of *E. coli*, only leucine tRNA_{II}, serine tRNA_{III}, tyrosine tRNA_i and tyrosine tRNA_{II} were active as primers. It is interesting that all active tRNAs possess the S-region in their secondary structure, and were eluted at the end of neutral DEAE-Sephadex A-50 chromatography⁹. It should be noted that serine tRNA_i, which was inactive as a primer, was eluted at the top region of DEAE-Sephadex A-50 chromatography, although it possesses the S-region. Thus the primer activity of tRNA molecules may be related to their structural properties which determine their positions of elution in DEAE-Sephadex A-50 chromatography.

The enzymatic reaction showed an absolute requirement for primer RNA (Table 2, experiment 1). The reaction was neither inhibited by creatine phosphate and creatine phosphokinase nor by inorganic phosphate, but was inhibited by inorganic pyrophosphate. This suggests that guanosine tri-

phosphate is the actual substrate. The three ribonucleoside triphosphates other than GTP were not required for incorporation of GMP. The enzyme required magnesium or manganese ions, the optimum concentration being 7–14 mM and about 5 mM, respectively, and it also required 2-mercaptoethanol, its optimum concentration being 0.08 mM. *E. coli* tyrosine tRNA_{II} lost all its primer activity after oxidation by periodate or after digestion with RNase T₁. When ribonucleoside triphosphates other than GTP were offered as substrates, no enhancement of incorporation was observed when tRNA was added (Table 2, experiment 2).

Various nucleic acids other than RNAs extracted from Ehrlich ascites tumour and *E. coli* were tested and found to be inactive as primers (Table 1). Moreover, none of these inactive RNAs was inhibitory to the enzyme reaction, as tested with *E. coli* tyrosine tRNA_{II} as the primer.

The radioactive product synthesised by the enzyme with tyrosine tRNA_{II} as a primer had a molecular size of about 4S as determined by glycerol gradient centrifugation. Treatment with alkali and RNases, such as RNase T₂, RNase T₁, RNase A and PDase (venom phosphodiesterase), made the radioactive product acid soluble. The radioactive substances in the hydrolysates as identified by cellulose thin-layer chromatography, Dowex-1 or DEAE-Sephadex A-25 column chromatography were as follows: alkaline hydrolysis, 2'-GMP and 3'-GMP; RNase T₂ treatment, 3'-GMP; RNase T₁ treatment, 3'-GMP and oligonucleotides; RNase A, oligonucleotides with chain lengths of more than two; and PDase treatment, 5'-GMP. The molecular ratio of incorporated GMP to the primer tyrosine tRNA_{II} reached a maximum of 10–15. These preliminary analyses of the products indicated that the radioactivity existed in GMP residues which were attached covalently to the primer tRNA by phosphodiester linkages. Determination of the structure of the radioactive product is now in progress.

The presence of primer RNA in Ehrlich ascites tumour and the absence in normal mouse liver (Table 1) prompted us to search for primer RNAs in other tissues and tumours of mouse. RNAs extracted from mouse spleen and kidney, as well as liver, were inactive as primers while RNAs extracted from tissues of mice infected with Friend virus or transplanted

Table 2 Characterisation of the reaction

Assay condition	³ H-GMP incorporated (pmol)
Experiment 1 Complete	44.8
–RNA	< 0.5
–Enzyme	< 0.5
–Enzyme+heated enzyme	1.2
+ATP, UTP, CTP (0.1 μmol each)	41.9

+Trypsin (20 μg)	10.0
+RNase A (10 μg)	< 0.5
+DNase (10 μg)	44.6
+Inorganic phosphate (1 mM)	51.8
(10 mM)	49.8
+Inorganic pyrophosphate (1 mM)	48.4
(4 mM)	29.6
(8 mM)	19.3
Experiment 2	(μg)
³ H-GTP+tyrosine tRNA ₁₁	1.3
+ glutamic acid tRNA ₁₁	2.5
³ H-ATP+tyrosine tRNA ₁₁	2.5
+ glutamic acid tRNA ₁₁	2.5
³ H-UTP+tyrosine tRNA ₁₁	2.5
+ glutamic acid tRNA ₁₁	2.5
³ H-CTP+tyrosine tRNA ₁₁	2.5
+ glutamic acid tRNA ₁₁	2.5

Heated enzyme was prepared by heating at 60 °C for 10 min. The complete reaction mixture was as described in the legend to Table 1, except that 30 μg of enzyme protein and 0.33 μg of purified *Escherichia coli* tyrosine tRNA₁₁ as a primer were added (experiment 1). The reaction mixtures in experiment 2 were similar to those in experiment 1 with these alterations: 0.1 μmol each of tritiated ribonucleoside triphosphates (2×10^6 c.p.m. per 0.1 μmol) was used as substrate; the amount of enzyme was 11 μg, and purified *E. coli* tRNA was added as a primer. In experiment 2, the radioactivity for the sample without added tRNA was subtracted from each value. Washed Ehrlich ascites tumour cells were suspended in lysis buffer (0.1 M Tris-HCl, pH 7.4, 0.01 M MgCl₂, and 0.0005 M 2-mercaptoethanol) containing DNase (5 μg ml⁻¹), and frozen and thawed once. After homogenisation for 40 s, the mixture was stirred at 4 °C for 30 min and EDTA was added to a final concentration of 0.01 M. The homogenate was then centrifuged at 105,000g for 2 h. From the supernatant the 35–50% (NH₄)₂SO₄ precipitate was collected and dissolved in lysis buffer, and the appropriate amount of protamine sulphate was added to remove nucleic acids. The 60% (NH₄)₂SO₄ precipitate was collected and dissolved in the standard buffer (0.01 M Tris-HCl, pH 7.4, 0.005 M MgCl₂, 0.0005 M 2-mercaptoethanol and 30% (w/v) glycerol). Remaining (NH₄)₂SO₄ was removed from the dissolved precipitate by passage through a column of Sephadex G-25, previously equilibrated with buffer (0.05 M Tris-HCl, pH 7.4, 0.001 M EDTA, 0.001 M 2-mercaptoethanol and 30% (w/v) glycerol). The flow-through fraction was applied to a phosphocellulose column (P11 Whatman), previously equilibrated with buffer. Elution was started with the equilibrating buffer containing 0.02 M NaCl, and then the concentration of NaCl was changed to 0.2 M. The 0.02–0.2 M NaCl fractions were pooled. The 60% (NH₄)₂SO₄ precipitate was collected, dissolved in the standard buffer and used as enzyme.

Table 3 Survey of primer RNA from mouse

Source of RNA	³ H-GMP incorporated (pmol)
Ehrlich ascites tumour	16.4
Spleen (normal)	1.5
(with Friend virus-induced solid tumour)	20.8
Liver (normal)	2.5
(Friend virus-infected)	15.6
(with Friend virus-induced solid tumour)	13.2
Kidney (normal)	3.2
Friend virus-induced ascites tumour	21.8
Sarcoma 180	19.0

Assay conditions were as described in the legend to Table 1. Enzyme added was 30 μg, and 20 μg of each RNA was added as a primer. RNAs were extracted from spleen and liver of mice infected with Friend leukaemia virus or transplanted with Friend virus-induced solid tumour and from Friend virus-induced ascites tumour, as described previously^{12,13}. Both the solid and ascites strains of Friend tumours were infected persistently with Friend virus¹⁴. Mice with sarcoma 180 were supplied by Kyowa Hakko Co., Ltd.

with Friend virus-induced solid tumour and RNAs from Friend virus-induced ascites tumour and sarcoma 180 were active (Table 3). Though the biological significance of this enzyme remains obscure, these results suggest that, in mouse, primer RNAs (probably specific tRNAs) are specific to tumours or tissues infected with tumour viruses.

Mutation blocking the specific degradation of reinitiation polypeptides in *E. coli*

A NONSENSE mutation in a bacterial gene leads to the synthesis of two kinds of incomplete polypeptides^{1–4}. These are the termination, or T, fragments extending from the normal N terminus to the site of mutation, and the reinitiation, or R, fragments initiating distal to the end of the T fragment and continuing to the normal C terminus. Both the T and the R fragments produced by nonsense mutations in the β-galactosidase gene of *Escherichia coli* (z gene) are rapidly and selectively degraded *in vivo*^{5–7}. This contrasts strongly with the wild-type β-galactosidase, which is stable^{5,7}. The degradation of mutant polypeptides implies the existence of proteolytic systems which can distinguish these unstable proteins from the stable ones.

One of the approaches our laboratory has taken to the study

Fig. 1 Genetic map of the *lac* operon of *E. coli*. p, Promoter; o, operator; z, the structural gene for β-galactosidase; y, the structural gene for galactoside permease; a, the structural gene for thiogalactoside transacetylase. The lines below indicate the extent of various deletions. Terminating mutations and π(1), the mutationally generated reinitiation site¹, are shown above the line. α and ω regions are only approximately defined by complementation. All of these mutants have been described^{9,10}. *degR* was isolated from a *recA*[–] diploid between deletion B9 and NG200. B9 ends before the operator but covers all known z[–] mutations at the operator end. This is a new observation about B9, as a result of finer mapping than in the original report¹¹.

of these degradation systems is to isolate mutations that lead to the stabilisation of T and R fragments. The first such mutation was isolated by a selective strategy based on intracistronic complementation⁸. The resulting mutation, originally named *deg* but now called *degT*, stabilises T fragments. We present results in this paper which show that *degT* mutations do not stabilise R fragments. This observation implies the existence of another degradation system which recognises R fragments. By modifying the original selection procedure we have been able to isolate a mutation, called *degR*, which stabilises R fragments against degradation but has little effect on T fragments.

To isolate mutants stabilising R fragments, a *recA*⁻ *F'* *lac* heterogenote containing two *z*⁻ mutations was constructed (see Fig. 1). These *z*⁻ mutations were picked to have such a low level of complementation that the diploid was *lac*⁻ on MacConkey *lac* indicator plates. This lack of significant complementation could be attributed to the rapid rate of degradation of the R fragment, since the T fragment was chosen for its relatively slow decay rate. The diploid was *rec*⁻ to prevent *lac*⁺ bacteria from arising by recombination. This *lac*⁻ diploid was allowed to revert, and on analysis some of the *lac*⁺ revertants were found to contain mutations affecting the degradation of the R fragment. The screening techniques were the same as previously used for *degT* (ref. 8). One of these *lac*⁺ revertants, *degR*₁, was studied extensively.

The effect of *degT* and *degR* on T fragments is shown in Fig. 2. The rate of decay of the NG521 nonsense T fragment is assayed by auto- α complementation¹². Clearly, the *degT* but not the *degR* stabilises this polypeptide. The effect of the

Fig. 2 Kinetics of degradation of a UGA termination fragment in *degT*, *deg*⁺, and *degR* strains. The degradation of termination fragments in exponentially growing cultures after removal of inducer was followed by assay of auto- α donor activity. The cells were grown in 100 ml of standard LB at 37 °C on a shaker, and during exponential growth IPTG (isopropyl- β -D-thiogalactopyranoside) was added to a final concentration of 5×10^{-4} M. After 15 min of induction, cells were centrifuged, washed twice with an equal volume of chilled LB, resuspended in warm LB; and the incubation was continued on a shaker. Samples (10 ml) were withdrawn at regular intervals before and after the removal of IPTG. The auto- α activity of the samples was measured as described by Morrison and Zipser¹². The β -acceptor extract was prepared from a strain carrying deletion 21 in the *z* gene. The amount of auto- α activity present immediately after the removal of IPTG was called 100%, and the percentage of auto- α activity remaining at later times was calculated accordingly. ○, auto- α of 521 (UGA) fragments in *degT* cells; ●, auto- α of 521 (UGA) in wild type cells; △, auto- α of 521 (UGA) in *degR* cells. The genotype of the strain is *F* *pro*⁺ *lac* *z*⁻ 521/*z*⁻ 521, with the exception of the *deg* marker.

two kinds of *deg* mutations on R fragments is shown in Figs 3 and 4. In one case ω complementation is used to follow decay, and in the other the ¹⁴C-labelled polypeptide is visualised by autoradiography after SDS-polyacrylamide gel electrophoresis. *degR* is seen to stabilise both the complementing activity and the physical structure of R fragments, whereas *degT* has no effect. This clear separation of the effects of *degR* and *degT* is typical. Occasionally there is some cross effect of *degR* on T fragments or *degT* on R fragments (Apte, B. N., and Zipser, D., unpublished). We believe this is not a direct effect but the result of stabilising interactions between T and R fragments themselves. Thus, for example, when a T fragment is stabilised by a *degT* mutation it can then interact with an

Fig. 3 Kinetics of degradation of ω complementing activity in *degT*, *deg*⁺, and *degR* strains. The cells were grown in 200 ml of standard LB at 37 °C on a shaker, and during exponential growth IPTG was added to a final concentration of 5×10^{-4} M. After 30 min of induction, cells were centrifuged, washed twice with an equal volume of chilled LB, and resuspended in warm LB; and incubation was continued on a shaker. Samples (20 ml) were withdrawn at regular intervals before and after the removal of IPTG. ω complementing activity was measured as described by Ullman *et al.*¹⁰ with some modification. The cells were collected by centrifugation; the pellet was suspended in 1 ml of TM buffer (0.01 M Tris, 0.01 M MgCl₂) and sonicated with a Biosonik IV sonicator. The sonicates were centrifuged, and 0.5 ml of the supernatant was mixed with 0.5 ml of ω acceptor extract from the *z*⁻ NG200 mutant. The mixture was incubated at 21 °C for 90 min and an aliquot was assayed for β -galactosidase activity. The amount of ω donor activity present immediately after removal of the inducer was called 100%, and the percentage of ω donor activity remaining at later times was calculated accordingly. ○, ω -donor activity in *degT* cells. ●, ω -donor activity in the wild type. △, ω -donor activity in *degR* cells. The genotype of the strain is *F* *pro*⁺ *lac* *z*⁻ 545- π (1)/*lac* *z*⁻ 545- π (1), with the exception of the *deg* marker.

R fragment to slow its degradation. A similar effect would be expected from stabilising R fragments.

The data in Fig. 4 indicate that the half life of the π (1) restart fragment increases from about 5 min in wild type to over 30 min in the *degR* background whereas the half life of the unstable ω complementing activity increases by at least the same factor. The apparent rate of synthesis of π (1) goes up about fourfold, as indicated by the amount of ¹⁴C-leucine incorporated in a 4 min pulse. There is also an increase of about 65% in the amount of β -galactosidase produced when a wild type *z* allele is put in the *degR* background. The cause of this modest increase is not known. It could be explained, however, if some nascent β -galactosidase was degraded by the R system in a wild type but not in the *degR* background.

The simplest interpretation of the data presented here is that *degR* is a mutation affecting some feature of the degradation system for R fragments in *E. coli*.

This investigation was supported by grants from the National

Fig. 4 Kinetics of degradation of reinitiation fragment in *degT*, *deg+*, and *degR* strains. The strains were grown in side-arm flasks containing 80 ml of minimal glycerol medium. The cells, at a density of approximately 5×10^8 cells ml^{-1} , were induced by addition of IPTG to a final concentration of 5×10^{-4} M. After 2 min of induction the culture was labelled for 5 min with $10 \mu\text{Ci}$ of ^{14}C -leucine ($312 \mu\text{Ci} \mu\text{mol}^{-1}$), at which point a 1,000-fold excess of cold leucine was added. Just before the chase and at regular intervals during the chase, 20-ml samples were withdrawn, centrifuged, resuspended in 0.5 ml of TM buffer, and sonicated. The samples were centrifuged, and $5 \mu\text{g}$ of pure β -galactosidase and $15 \mu\text{l}$ of anti- β -galactosidase serum were added to each sample. The samples were allowed to stand at 4°C for 2 h, after which they were centrifuged and the antigen-antibody complex washed three times with TM buffer. The pellet was finally dissolved in $50 \mu\text{l}$ of SDS sample buffer by heating at 100°C for 10 min. Fifteen microlitres of each sample were loaded on 10% SDS-polyacrylamide gel slabs, which were made and run according to Studier¹² with the discontinuous buffer system of Laemmli¹³. The gels were stained, dried, and autoradiographed on Kodak medical X-ray film. The film was scanned with a Joyce-Loebl microdensitometer. The areas under $\pi(1)$ peaks in different samples, representing the amount of radioactive $\pi(1)$ fragment present, were normalised with respect to another stable peak in all samples. The amount of fragment just before the chase was called 100%, and the percentage of radioactive fragment remaining at other times during the chase was calculated accordingly. \circ , Degradation of $\pi(1)$ in *degT* cells; \bullet , degradation of $\pi(1)$ in the wild type; \triangle , degradation of $\pi(1)$ in *degR* cells. A part of the autoradiogram from which the data for the decay curves were obtained is shown in the upper right corner of the figure. *a*, Degradation of $\pi(1)$ in *degT* cells; *b*, degradation of $\pi(1)$ in *deg+* cells; *c*, degradation of $\pi(1)$ in *degR* cells. The time at which the sample was taken is indicated below each sample. The genotype of the strain is $F' \text{ pro}^+ \text{ lac } z^{-545} \cdot \pi(1) / \text{lac } z^{-545} \cdot \pi(1)$, with the exception of the *deg* marker.

Fourteen actin-binding sites on tropomyosin?

TROPOMYOSIN plays an important part in the control of muscle contraction. It is a rod-shaped, coiled-coil molecule, about 410 Å long, composed of two parallel α -helical chains which are in register¹⁻⁴. It lies in the grooves of the actin double helix of all known types of muscle filament and is normally thought to be associated with seven actin units⁵⁻⁷. Calcium regulates the contraction of vertebrate skeletal muscle by its influence on troponin, which in turn leads to a movement of tropomyosin in the actin groove⁸⁻¹⁰, thereby exposing (in the 'on' position) or masking (in the 'off' position) the myosin cross-bridge binding areas. The position of the troponin-binding site is known fairly precisely (ref. 11 and review ref. 4), but the actin-binding sites have not yet been identified. Here, we analyse a fourteen-fold periodicity in the amino acid sequence of α -tropomyosin¹² from rabbit skeletal muscle and propose that it is associated with seven pairs of quasi-equivalent actin-binding sites. Parry¹³ and Stone *et al.*¹² first noted several series of amino acid types with a repeat of about $19\frac{1}{2}$ residues, and areas low in acidic residues spaced about 40 residues apart. There is also a slightly irregular 42-residue repeat resulting

Fig. 1 Fourier transform of the acidic residues of tropomyosin. Note the periodicity at 19.73 residues in addition to the second and third orders of the heptapeptide repeat at 3.5 and 2.3 residues. The transform was computed by expressing the chemical sequence¹² as a mathematical sequence of ones (for acidic residues) and zeros (for the rest) and, to enhance the fine detail of the transform, this was made the first 284 terms of a sequence of 2,048, the rest of which were zero. To enable different transforms to be compared directly, the mean of this sequence was adjusted to zero and its root mean square scaled to an arbitrarily chosen value of 10 before transformation.

Fig. 2 Average composition of the acidic residue repeat unit (two consecutive repeats shown). The origin corresponds to the N-terminus of the sequence or points multiples of 19.73 residues from it. The distribution was computed by convoluting the mathematical sequence with a series of points spaced 19.73 residues apart. This is equivalent to adding the sequence to itself with staggers of 19.73 residues.

from gene duplication¹⁴ which is in phase with them. We used Fourier analysis to make an objective and systematic search for periodicities in the distributions of acidic, basic and non-polar groups, and here assess their significance.

Figure 1 shows the Fourier transform for the acid groups, which shows a strong periodicity at about 20 residues. By expanding the series to 17,040 terms the peak was fixed at between 19.722 and 19.745 residues, and we take 19.73 as the best estimate. The non-polar and basic distributions showed a much weaker variation 180° out of phase with the acid profile. Table 1 gives their amplitudes and phases. A detailed hand examination confirms that the periodicity persists along the entire sequence. Figure 2 illustrates the average distribution of acid groups in the 19.73-residue period and shows that they are grouped into bands about 10–12 residues wide. Thus our study shows that the periodicity is closer to 19.73 than 19½ residues, and is strongest in the negative charges. There are also marked periodicities at 7/2 and 7/3 residues, which appear because the supercoiling of the helix depends on a heptapeptide repeat pattern in the sequence^{2,12,15} of the type *a.b.c.d.e.f.g*. Residues at positions *a* and *d* are normally non-polar, at *e* often acid, and at *g* basic.

It is important to establish whether the 19.73-residue periodicity could arise by chance. To do this, artificial tropomyosin sequences were constructed by shuffling residues between heptapeptides. Residues in positions of type *a* were shuffled randomly, as were those of type *b*, and so on, producing sequences in which the heptapeptide pattern persisted but other features were randomised. These sequences were then transformed and their amplitude at a frequency of 19.73 residues determined as for the tropomyosin sequence. For the acidic residues the average value of this amplitude for 5,000 such sequences was 8.9 with a standard deviation of 4.6. The maximum value obtained was 29.4 and 99.9% of the values were less than 25.5. Therefore, the value of 31.7 obtained at this frequency for the acidic residues in the real sequence is highly significant. The low value obtained for the basic residues is clearly not significant, but the significance of the value of 20.4 obtained for the non-polar residues is not immediately clear, because the fact that these residues will only be found in the gaps left by the acidic periodicity will tend to produce a periodicity even if they occupy the gaps randomly. To test this point, random sequences were again generated, but only the positions of the basic and non-polar residues were randomised within the heptapeptide structure; the positions of the acidic residues were not changed. The mean value of the amplitude at 19.73 residues for 5,000 such sequences was 18.8 with a standard deviation of 4.3 and 27% of these values exceeded the value of 20.4 obtained with the real sequence. Thus the non-polar repeat may only be a consequence of the

Table 1 Amplitudes and phases of the transforms of the tropomyosin sequence at a frequency of 19.73 residues

	Type of residue		
	Acidic	Basic	Non-polar
Amplitude (arbitrary units)	31.7	12.0	20.4
Phase (degrees)*	13.5	168	–155

* Referred to a phase origin at the N-terminus of the sequence.

repeat in the acidic residues. A hand examination of the sequence, however, reveals some regularities in the non-polar groups at positions *b*, *c*, *f* of the helix which suggest that these groups are themselves significant.

How is the 19.73-residue length related to the structure of tropomyosin itself, and its interaction with actin? Its chains appear to be in register, so the end-to-end association of tropomyosin is thought to involve an overlap of molecular ends^{3,16}. The 19.73-residue pattern will repeat 14.39 times in 284 residues (the length of the sequence¹²) and so, if the molecules were joined without overlap, the periodicity would be interrupted on passing from one molecule to the next. Observations on paracrystals¹⁰, together with the points mentioned below about the interaction with actin suggest that there should be no interruption. This implies an overlap of about eight residues, when the apparent length of the molecule would be 276 residues, 14 times the repeat distance. If the axial residue length in tropomyosin is taken as 1.49 Å (ref. 17) a sequence of 276 residues would have a length of 411 Å, instead of 423 Å for 284 residues, which would agree well with the value of 410 ± 5 Å found in crystals⁴.

In its interaction with actin, the three-dimensional structure of tropomyosin is important. Longley¹⁸ has proposed that the tropomyosin coiled coil makes seven half turns in a molecular length. We prefer the view¹⁶, endorsed by Parry¹⁹, that there are only six half turns, so that the coiled coil makes seven half

Fig. 3 Scheme for the binding of tropomyosin to actin. *a*, Arrangement of proteins in the thin filament; *b*, interaction of seven actin units with a tropomyosin molecule. This projection corresponds to unwinding the actin helix in (*a*) so that the seven shaded actin units lie in a straight line. This operation preserves the relative positions of the actin and tropomyosin interaction sites but imparts an additional half turn to the tropomyosin coiled coil so that its apparent pitch in this projection is reduced to 114 Å as opposed to 137 Å in the thin filament. The 28 negative zones on the tropomyosin molecule (indicated on the coiled-coil by dense regions) are arranged in four series of seven and one of these series is placed so that each of its zones makes an equivalent contact with an actin unit.

turns relative to the actin subunits when it follows the twist of the actin helix in the thin filament. With the chains in register, the 14 acidic zones on each chain come together to give 28 acidic surface zones on the outside of the tropomyosin supercoil which form 14 diametrically opposed pairs 29.3 Å apart. Each pair of zones has a twist of 90° relative to the next (Fig. 3) so that the 28 zones form four series of seven when viewed along the direction of the actin helix. The zones of one of these series are spaced so that they can interact with seven consecutive actins on one side of the actin groove and it would therefore seem likely that the acid-rich zones represent the regions of the tropomyosin which bind ionically to actin, while the non-polar groups may make additional hydrophobic contacts. The 14 zones probably represent two different series of binding sites, with one set of seven being used in relaxed muscle ('off'), and one or both in the tense state ('on'), when tropomyosin changes its position⁸⁻¹⁰. The sites on adjacent zones may be so placed as to interact with both strands of the actin helix, since the projection of the 29.3 Å zone spacing also matches the axial stagger between actins. The three-dimensional reconstructions of actin-tropomyosin²⁰ seem to be consistent with these proposals.

An analysis (which will be published elsewhere) of the staining patterns in magnesium paracrystals indicates that the molecules lie with their acid-rich zones opposite one another, and suggests that magnesium bridges between opposing zones are a major source of stability in these structures. The same type of bridge would be expected to form in actin paracrystals²¹ which also appear with magnesium. As magnesium ions seem to be necessary for the binding of tropomyosin to actin (except in strong salt solutions)^{22,23} we propose that the tropomyosin-actin interaction involves magnesium bridges between zones of negative charge on both molecules, although there may also be direct salt bridges to positive zones on actin. As the charged amino acids have long flexible side chains, both types of linkage could couple residues several Å apart. This could explain the irregularities in the composition of the acidic zones of tropomyosin, since for the linkage to form it would only be necessary for the particular residue on tropomyosin to lie in a general area (probably three or four residues long).

We thank Professor L. B. Smillie for showing us his work on the sequence of tropomyosin before publication, Dr D. A. D. Parry for correspondence and our colleagues for helpful criticisms and comments. M. S. acknowledges the financial support of the Wellcome Trust and A. D. Oxygen affinity and allosteric effects of embryonic mouse haemoglobins

THE formation of a circulatory system in the ontogeny of mammals coincides with the appearance of nucleated erythroid cells which are produced in the blood islands of the yolk sac. These cells contain specific embryonic haemoglobins (Hbs) which probably transport oxygen during the earliest stages of mammalian development. Such embryonic Hbs have been demonstrated in man¹⁻⁵ and several other mammalian species⁶⁻⁸. Structural investigations of these pigments showed them to be tetramers which contain unique α -type or β -type subunits. It was also shown that the embryonic α -type subunits of man, mouse and rabbit have more sequence similarity among each other than between the embryonic and the adult α subunit of the same species, indicating that the divergence of embryonic and adult α subunits is much older than mammalian evolution⁹.

This fact is contrasted by sparse data on their function. Farooqui and Huehns⁹ have obtained oxygen dissociation curves on nucleated erythroblasts of human embryos which contained more than 30% embryonic Hbs, and found no significant difference compared with the oxygen-binding properties of human foetal red cells. Studies on the oxygen equilibrium and the Bohr effect of pure Hb Portland revealed, however, that the intrinsic oxygen affinity of this human embryonic Hb is higher than that of adult Hb¹⁰. We show here that the oxygen affinity of mouse embryonic Hbs in the presence of physiologically significant allosteric effectors is considerably higher when compared with adult mouse Hb and that Hb Portland and the embryonic mouse Hbs share some important respiratory characteristics.

Erythroid cells obtained from the peripheral blood of 12.5 d-old mouse embryos¹¹ (strain BALB/c) were washed in saline, lysed by sonification at 4 °C, and the haemolysate centrifuged to remove the cell debris. The clear supernatant was then passed over Sephadex G25 columns equilibrated with bicarbonate or *bis*-Tris buffer for oxygen-binding experiments in the presence and absence of CO₂, respectively. When examined by isoelectric focusing electrophoresis or ion-exchange chromatography on CM cellulose, the haemolysate contained three embryonic Hbs: Hb E_I (50%), Hb E_{II} (30%), Hb E_{III} (16%) as well as traces of adult Hb. Hb E_I consists exclusively of embryonic subunits, whereas Hb E_{II} and Hb E_{III} each contain a pair of adult α subunits^{6,8,12}. Oxygen-binding properties of the unfractionated haemolysate were examined spectrophotometrically in a diffusion chamber^{13,14} at 37 °C and the results compared with those obtained with Hb solution from adult mice (BALB/c) which had been purified by repeated passage over a mixed-bed ion-exchange resin, and then on Sephadex G25 columns.

The partial pressure of oxygen at which Hb is half-saturated (P_{50}) was lower in embryonic than in adult Hb (10.5 and 17 mm Hg, respectively; *bis*-Tris buffer, pH 7.2) which means that the intrinsic oxygen affinity of mouse embryonic Hb is higher than that of the adult pigment (Fig. 1), which was also found in Hb Portland¹⁰. In addition, the change in P_{50} with varying pH in the alkaline range was less pronounced in embryonic than in adult mouse Hb ($\Delta \log P_{50} / \Delta \text{pH} = -0.36$ and -0.48 , respectively). Cooperativity of oxygen binding was, however, similar in both pigments when judged from the exponent n in Hill's equation¹⁵ ($2.6 < n < 3.0$). Perhaps the most striking difference between adult and embryonic Hb with respect to the oxygen-linked proton binding is the shift of the so-called reversed Bohr effect towards neutral pH in embryonic Hb (Fig. 1). We interpret this phenomenon biologically as being advantageous for the embryo as a decrease in pH below 7.25—that is, in a severe acidosis—causes no further fall in oxygen affinity and therefore no impairment of its oxygen uptake. Oxygen release from adult Hb on the other hand, is facilitated in such a situation. The same diminished reactivity towards oxygen-linked

Fig. 1 Plot of $\log P_{50}$ against pH of adult (\circ) and embryonic (Δ) mouse Hb. Temperature, 37°C ; Hb concentration, 0.3×10^{-3} M per 1 tetramer; buffers, 50 mM *bis*-Tris–100 mM NaCl at $pH \leq 7.5$ and 50 mM Tris–100 mM NaCl at $pH > 7.5$. Neither preparation of adult or embryonic Hb samples contained DPG when evaluated by a kinetic test procedure¹⁸.

protons has been observed with Hb Portland, where $\Delta \log P_{50} / \Delta pH$ is only half as large as in adult human Hb¹⁰. A further similarity concerns the reversed Bohr effect which becomes effective at about pH 7 in both types of embryonic Hb and not at pH 6, as it does most mammalian Hbs including human foetal Hb.

Apart from protons, there are at least two more allosteric agents, CO_2 and 2,3-diphosphoglycerate (DPG) which influence the oxygen affinity of Hb. On addition of CO_2 ($P_{\text{CO}_2} = 40$ mm Hg) at pH 7.2, $\log P_{50}$ increased from 1.02 to 1.12 in embryonic and from 1.23 to 1.46 in adult Hb (Fig. 2). This rather weak effect of CO_2 on embryonic mouse Hb suggests that the N-terminal α -amino groups, where oxygen-linked carbamate is being formed¹⁶, are less accessible for CO_2 compared with adult Hb, possibly because the N-terminal amino groups of some subunits are blocked. The maximal effect of DPG on the oxygen affinity of adult and embryonic mouse Hb was about equal when judged from the shift in $\log P_{50}$ produced by DPG (Fig. 2 a). The combined effect of both chemicals was such that at a given concentration of DPG, P_{50} for embryonic Hb was slightly lower in the presence of CO_2 than in its absence, whereas P_{50} of the adult Hb increased even further (Fig. 2 b). It thus became evident that at physiological pH and temperature the high oxygen affinity of embryonic Hbs is maintained in the

Fig. 2 Plot of $\log P_{50}$ at various concentrations of DPG of adult (\circ , \bullet) and embryonic (Δ , \blacktriangle) mouse Hb. a, No CO_2 , b, P_{CO_2} is 40 mm Hg. Temperature, 37°C ; pH 7.2; Hb concentration, 0.3×10^{-3} M per 1 tetramer; buffers, 50 mM *bis*-Tris and 100 mM NaCl in the absence of CO_2 (a), and bicarbonate–NaCl buffer with a molarity of 150 mEq l^{-1} in presence of CO_2 P_{CO_2} 40 mm Hg, (b). DPG used as sodium salt.

presence of allosteric effectors which are likely to be of significance for the control of the oxygen affinity in embryonic blood.

To estimate the influence of pH , CO_2 and DPG on the oxygen affinity of Hb *in vivo*, one needs actual measurements of these variables. As far as pH and P_{CO_2} are concerned it is impossible to collect blood anaerobically from 12.5-d-old mouse embryos in quantities sufficient for the analytical procedures now available. On measuring DPG concentration, which requires less material, in embryonic blood, we found 1.35×10^{-3} M DPG per 1 nucleated erythroid cells compared with 10.8×10^{-3} M DPG per 1 adult erythrocytes. As both Hb and DPG are likely to be present only in the cytoplasm of the erythroid cells one has to correct the former value by the volume taken up by the nucleus. From a large number of measurements of the diameter of the nucleus we estimated its volume to be $250 \mu\text{m}^3$, assuming a spherical shape. Mean cellular volume of the erythroid cells was $470 \mu\text{m}^3$ so that the corrected DPG concentration is 2.9×10^{-3} M DPG l^{-1} . The mean cellular Hb concentration in the cytoplasm of these nucleated erythroid cells is 27%, giving a molar ratio of DPG to Hb tetramer of about 0.7, compared with about 2.0 in the erythrocytes of adult mice. We conclude that the concentration of DPG in erythroid cells is high enough to produce a significant decrease in oxygen affinity.

Our results show that in all experimental conditions investigated, embryonic Hb has a much higher oxygen affinity than the adult form. We conclude that the respiratory function of blood during the very early stages of mammalian ontogeny has characteristics which tend to facilitate embryonic oxygen uptake.

More structural and functional analyses of embryonic Hbs should provide an answer to the question of whether the high oxygen affinity of these respiratory proteins is a selective factor in evolution, as seems to be the case for the salient allosteric effects of adult Hb¹⁷. In favour of such an assumption is the similarity of intrinsic oxygen affinity and Bohr effect of mouse and human embryonic Hbs.

Conformation of thyroid hormone analogues

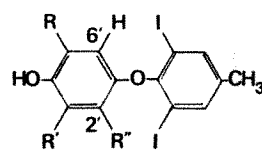

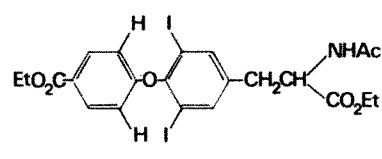

COMPARISON of the activities of conformationally 'fixed' derivatives of thyroid hormones has led to the proposal that the active conformation of 3,5,3'-triiodo-L-thyronine (L-T_3) is one in which the 3'-iodine is distal to the inner (α) ring^{1–4} (Fig. 1). These conclusions have prompted several X-ray studies aimed at determining the conformational preference in the crystals of thyroid hormones^{5–10}. Such studies have shown that the posi-

tioning of the 3'-iodine in the crystal structures of L-T₃ and related compounds is dependent on the crystallising medium, thus suggesting that the distal and proximal forms of L-T₃ are of similar energy. These findings prompted us to investigate the temperature dependence of the proton nuclear magnetic resonance (NMR) spectra of thyroid hormone analogues to determine, in solution, both the magnitude of the barrier to rotation around the ether oxygen and, in unsymmetrical molecules, the relative populations of distal and proximal forms.

Previous work¹¹ on 2,6-diisopropylidiphenyl ethers, together with reported steric parameters for iodine and isopropyl¹², suggested that the coalescence temperature for the 2',6' proton signals of thyroid hormones would be below -60 °C. Since, at this temperature, the thyroid hormones would be practically insoluble in most solvents, we chose, instead, to investigate the model compounds (1-4 in Table 1). The steric and electronic consequences of replacing the alanine side chain by a methyl group are not expected to affect markedly the intrinsic rotational properties of the ether bond⁴. Nevertheless, we recognise that this may alter the dipole moment of the molecule and that this in turn may affect the conformer population in solvents of high dielectric constant¹³.

The 60-MHz spectrum of the thyroxine model compound (1) (Table 1), in tetrahydrofuran, shows a time averaged singlet (7.18 p.p.m.) for the 2',6' protons at 40 °C. On cooling, this

Spectra were recorded on a Varian A60A (60 MHz) spectrometer in sodium dried tetrahydrofuran. Estimated errors in ΔG were based almost exclusively on uncertainties in T_c.

singlet broadens and eventually separates into two broad peaks (6.57 and 7.84 p.p.m.) (Fig. 2). At the coalescence temperature (-94 °C) a rotational barrier (ΔG₁₇₉[‡]) of 8.5 ± 0.2 kcalorie mol⁻¹ was calculated (Table 1) from the Eyring Equation¹⁴.

At 40 °C, the spectrum of a solution of the T₃ model compound (2) in tetrahydrofuran shows a typical ABC pattern for

Fig. 1 Distal (a) and proximal (b) conformations of T₃ analogues.

Fig. 2 Variable temperature NMR spectra of compound (1).

the 2', 5' and 6' protons (Fig. 3). The spectrum was analysed with the aid of a simple ABC computer program which provided accurate chemical shifts¹⁵. On cooling the solution to -108 °C, at which temperature rotation about the C(1')-O bond was slow on the NMR time scale, we expected to see the original ABC pattern replaced by two overlapping ABC patterns. Only signals for the individual 2'-protons in each of these two ABC patterns can be easily distinguished, however. Thus the 2' proton (7.1 p.p.m.) separates into two broad single peaks (6.5 and 7.72 p.p.m.) of equal intensity (Fig. 3). At the coalescence temperature (-105 °C) a rotational barrier (ΔG₁₆₈[‡]) of 7.9 ± 0.3 kcalorie mol⁻¹ was calculated (Table 1). At -108 °C the 6' proton separates into two broad peaks with approximate shifts of 6.1 and 7.3 p.p.m. (Fig. 3). The T₂ derivative (3) showed only exchange broadening of the 2',6' proton signals at the solvent limit of -110 °C, indicative of a barrier to rotation (ΔG₁₆₃[‡]) of less than 7.7 kcalorie mol⁻¹.

It is apparent from these results that rotation around the ether bond is governed by non-bonding interactions between the 2',6' hydrogens and 2,6 iodines. If it is assumed that the entropies of activation (ΔS[‡]) for rotations in compounds (1) and (3) are small^{14,16,17} or similar¹⁸ then comparison of ΔG_c[‡] (Table 1) for these two compounds suggests a slightly larger value for the T₄ derivative (1). This difference, if real, is probably caused by the buttressing effect of the 3',5' iodines on the 2',6' hydrogens, an effect previously observed in substituted biphenyls¹⁸. An indication that electronic factors may also affect rotation, as in other systems¹⁷, is suggested by the higher barrier to rotation (ΔG₁₉₄[‡] = 9.3 ± 0.2 kcalorie mol⁻¹) found for the diester (5, Table 1) compared with that of the phenol (3), assuming ΔS[‡] is similar for these two derivatives.

The 2' proton signals in the low temperature (-108 °C)

spectrum of the T_3 model compound (2) were of approximately equal intensity (Fig. 3), indicating an almost equal population of distal and proximal conformations. This represents the first experimental evidence indicating the existence of two conformations of T_3 or one of its analogues in solution. In extrapolating these low temperature results to biological temperature, it was necessary first to determine the variation of the weighted average chemical shifts of the 2' and 6' protons of (2) with temperature in the absence of changes in conformer population. Graphical plots showed that all protons in compounds (1-4) suffered chemical shift changes due to the influence of a common solvent effect. The results for compounds (3) and (4) are of particular interest since they involve only one conformation. The chemical shift of the proximally positioned¹⁹, 6' proton of the 2'-methyl derivative (4) showed a shift towards low field of only 5 Hz over the range +40 to -110 °C. The average chemical shift of the 2' and 6'-protons of (3) showed a similar change. We can conclude from these results that both proximal (2',6') and distal (2',6') protons show conformationally independent chemical shift changes with temperature, but these changes are likely to be (a) small compared with the chemical shift difference between 2' (or 6') proximal and distal protons and (b) similar for proximal and distal protons, that is, the chemical shift difference ($\Delta\nu$) is largely temperature independent. These results enable us to calculate distal-proximal ratios at different temperatures from the equation

$$n_D = \frac{(\nu_{W2'H} - \nu_{W6'H}) + (\nu_{D6'H} - \nu_{P2'H})}{(\nu_{D6'H} - \nu_{P6'H}) + (\nu_{D2'H} - \nu_{P2'H})} \quad (1)$$

where n_D = mole fraction of distal form, and ν_D , ν_P and ν_W refer respectively to distal, proximal and weighted average

chemical shifts. ν_D and ν_P were obtained from the single spectrum of (2) at -108 °C (Fig. 3) and n_D is calculated at any higher temperature by measuring $\nu_{W2'H} - \nu_{W6'H}$ at that temperature. On substituting $\nu_{W2'H} = 427.3$, $\nu_{W6'H} = 393.7$, $\nu_{D6'H} = 435$, $\nu_{P6'H} = 367$, $\nu_{D2'H} = 463$ and $\nu_{P2'H} = 390$ Hz into the above equation, n_D (40 °C) is calculated to be 0.56 (range 0.5-0.6 after taking account of experimental error); this indicates that there is very little change in the conformer ratio over the temperature range studied.

In summary, these results indicate that the barrier to rotation around the ether oxygen in thyroid hormones is in the range 7-9 kcalorie mol⁻¹, in reasonable agreement with a calculated⁴ barrier (11 kcalorie mol⁻¹) for T_3 . Furthermore, the observation of approximately equal populations of distal and proximal forms of the T_3 analogue (2) is not incompatible with an 'active' distal form, as suggested previously^{2,3}.

A recent communication by Camerman *et al.*²⁰ reported the observation of a single species of 3,5,3'-triiodothyropropionic acid in a mixture of diethanolamine, urea and methanol, but claimed to have shown the presence of two non-interconvertible conformations in a 2:1 mixture of ethanol-1 N HCl at room temperature. We believe that this work is in error as, first, the reported shift difference (1.7 Hz) between the 2' proximal and distal protons is negligible compared with those observed by us and other workers¹¹ and, second, the barrier to rotation, reported to be in excess of 20 kcalorie mol⁻¹, is far higher than expected. These apparently anomalous results are readily explained, however, if one assumes partial esterification of the acid by the acidic ethanol used as solvent.

Errata

In the article "Eccentricity-specific dissociation of visual functions in patients with lesions of the central visual pathways" by E. Pöppel *et al.* (*Nature*, **256**, 489; 1975) Fig. 1 and its legend should have been deleted and do not refer to the paper as published.

The title of the article (*Nature*, **256**, 750; 1975) by B. Donzel *et al.* should have read "Synthesis and conformations of hypothalamic hormone releasing factors: two TRF-analogues containing backbone N-methyl groups" and not as printed.

matters arising

February–June weather relationships in Norway

GREEN¹ claims that the empirical prediction technique can be useful in the development of long range weather forecasting. Empirical methods of long range forecasting sometimes follow the discovery of relationships between observations made at different times and places. Though I agree with Green that there seems to be no reason not to use the relationships in prediction, even though the physical mechanism behind them is not fully understood, some precautions must, nonetheless, be taken. If empirical correlations are to be of any value in weather forecasting, correlation coefficients ought to be considerably larger than the significance levels.

Green illustrated his idea using as an example the correlation between February and June temperatures at Dalen in Norway, between 1940 and 1974. He claims that a cold February will be followed by a warm June. Figure 1, however, shows that points are quite scattered.

An analysis of observed winter and summer temperatures in Scandinavia indicates that no correlation exists that can be useful for a forecast model. Fairbridge² has given differences between July and preceding January temperatures in Stockholm from about 1750. The data indicate a decline in amplitude during the nineteenth century, but a marked increase in recent years.

Table 1 shows the results of a correlation analysis of monthly temperatures at Dalen in Norway. The significance limit is based on a confidence

Fig. 1 Relationship between February and June temperatures at Dalen, Norway between 1940 and 1972. *a*, Computed from February–June temperatures for the period 1940–72; *b*, based on the same temperatures except those indicated by circles, showing that the negative correlation depends strongly on a few extreme temperature conditions.

level equal to 95%, in the Student's *t* distribution, and the coefficient is given only when it exceeds the significance limit. For the complete series, 1890–1972, there is no significant correlation between the February–June temperatures. Only by considering a shorter period back from 1972, can a significant correlation be found. Nor is the correlation between the lowest and the highest monthly temperature in the year significant. Similar results have been found in Oslo and Hellisøy.

Table 1 Empirical correlation coefficients for monthly temperatures at Dalen, Norway, between 1890 and 1972

	Jan.	Feb.	Mar.	Apr.	May	June	July	Aug.	Sept.	Oct.	Nov.	Dec.

November											1.00	0.37
December												1.00

* Significance limit $r_s = 0.22$.

In Britain³ and Norway, the monthly rainfall and temperature are correlated positively in winter and negatively in summer. If a negative correlation between February and June temperatures exists, a positive correlation between February temperature and June rainfall can be expected. An analysis of June rainfall and the temperature of the preceding months for three different places, Oslo, Dalen and Bergen reveals no significant correlation except for February temperatures in Bergen, in which the empirical correlation coefficient is just on the significance level.

I conclude that there is no statistical evidence that the winter temperature is a useful element in forecasting the summer temperature and rainfall for the same domain.

Development of visual acuity and the sensitive period

WE have read with interest the article, by Freeman and Marg¹. Their observations that there is a significant change in the response of the visual system of the kitten to spatial gratings with age are not unexpected from the results of our study of the optical properties of kitten's eyes. We question, however, their contention that, on the basis of their ophthalmoscopic observations, "it is unlikely that optical factors limit the acuity determined for younger animals." As evidence to the contrary, we submit the following.

Photographs of the fundus of the same kitten 11, 18, 25 and 32 d after birth are shown in Fig. 1. These photographs were made with a Zeiss fundus camera and accurately demonstrate the hazy media one encounters in kittens for the first 5 weeks of life. This haziness results from the scattering of light by the cornea which is not optically clear in the first 3–4 weeks of life, the tunica vasculosa lentis and by particulate material in the vitreous, much as is seen in premature infants (A. McCormack, personal communication). The tunica vasculosa lentis disappears between days 30 and 35 of life and not before day 23 as contended by Freeman and Marg. To quantify the

degradation of an image by the media of the eye, we have made densitometric measurements of a fluorescein-filled vessel in the posterior pole of the eye. Between days 25 and 32, there was a 43% decrease in the spread of the image of the vessel in the absence of any change in the refractive power or the axial length of the eye. These observations demonstrate that the optical quality of the kitten's eye is improving over this period and must play a significant part in determining the acuity of kittens.

Fig. 1

Further, there is another important factor about the kitten's eye which must be considered by the visual physiologist. We have determined, by retinoscopy, the refractive error of eight eyes from seven kittens. During the first eight weeks of life, with the accommodation paralysed by atropine, the mean refractive error is 7.62 D (range +15.00 D to +4.00 D). It should be noted that these are refractive error determinations for an object at infinity, and any object placed closer will require the kitten to use its accommodative power, which may be limited by the anterior displacement of the lens and its envelopment by the tunica vasculosa lentis. Thus, for example, if the kitten with a 7.50 D hyperopia were placed in the middle of a 50-cm diameter striped cylinder, it would be required to employ 11.5 D of accommodation to bring the stripes into focus. For the reasons cited above, we do not believe the kitten possesses anywhere near this accommodative power. It is indeed surprising that, in spite of these optical defects, it is possible to alter the development of receptive field properties of cortical cells², although these results have not been confirmed (M. P. Stryker and H. Sherk, unpublished). For an out-of-focus optical system with a vertical slit pupil, vertical objects will be in better focus than horizontal objects. If the kitten's visual system responds as does the human astigmatic eye³, the question arises, why are there not more vertically tuned cortical cells in normally

reared cats?

³ Mitchell, D. E., Freeman, R. D., Millodot, M., and Hagerstrom, G., *Vision Res.*, **13**, 535-558 (1973).

FREEMAN AND MARG REPLY—Accommodation and refractive error has nothing to do with our study as has been suggested¹. The kittens were under general anaesthesia and the eye and its protective contact lens were optically corrected for the 57-cm screen distance.

Optics has a great deal to do with the development of kittens and the determination of their sensitive or critical period of development. It is by means of slits, bars, and edges that the concepts of visual development and deprivation have been uncovered. The original work of Hubel and Wiesel² demonstrated orientation of cortical receptive fields in the kitten as young as 8 d, and others have done similar experiments. The optics of these eyes must be transmitting those forms.

There is no question that the optics of the kitten's eye improves up to about the fifth week, but this does not mean that it is the limiting factor in acuity. With good illumination (rather than a fluorescent source) retinal vessels of about 0.5° width can be resolved at 3 weeks of age. It is likely that the optics are transmitting to the retina gratings of similar detail.

While we await the results of systematic optical modulation transfer function data from the kitten, we stand by our original statement:

"It is clear that the optical quality of the eye of the very young kitten is inferior to that of the adult. But on the basis of ophthalmoscopic observation we feel that it is unlikely that optical factors limit the acuity determined for the younger animals."

Basalt from DSDP holes

ALTHOUGH Hammond *et al.*¹ are concerned mainly with palaeolatitudes of the Ontong Java Plateau, where DSDP 289 was drilled, they give considerable attention to the basalt at the bottom of the hole. At long last it is good to see another radiometric age for basalt, no matter how flawed the age may seem to the authors. The latter "assign" an age of 109 Myr to

the basalt on the assumption that it must be older than sediments above it which are dated as 108 Myr on biostratigraphic grounds. They find that the radiometric age of 80 Myr which they actually obtain is in "error", and they cite a similar error in a radiometric analysis performed by Cox and Dalrymple² to conclude that the "estimated analytical standard deviation arises almost entirely from uncertainties in the potassium measurements".

I can only suggest that uncertainties cut both ways. If a basalt dated at 80 Myr is to be corrected to 109 Myr it could just as well be corrected in the opposing direction to 51 Myr. In the latter case the basalt would be a sill. Needless to say the basalt would also be a sill if the authors were willing to accept their own date. As to their citation of Dalrymple and Cox I myself would cite MacDougall³. He found a basalt below Campanian strata in DSDP 10, western Atlantic, that gave a radiometric age of 16 Myr. The result was acceptable to MacDougall, from which one concludes that the basalt of DSDP 10 is a Miocene sill intruded into Campanian strata.

Those are the facts; however, impressions may not be out of place. The authors give me the impression that they are "bound and determined" to have the basalt as the oldest material in DSDP Hole 289. Why? Almost certainly because they assume that the basalt is basement. That is a common assumption in modern tectonophysics, but in my opinion it needs to be refuted vigorously. The fact that a few fragments of basalt are the oldest material in a particular hole has no connection with its crustal nature. If the basalt in DSDP were 218 Myr old instead of the assessed 109 Myr old there could still be 1,000 m of little-disturbed strata below. In short, the age of the ocean basins is a problem as wide open now as it was when DSDP drilling began.

In the last analysis my observations are addressed not so much to Hammond *et al.* in particular as to shipboard scientists in general. The scientists seem to go to sea convinced and/or indoctrinated that every piece of basalt is not only the bottom of the stratal sequence but also the bottom of the world. I have no proof to offer that their conviction and/or their indoctrination is incorrect. I submit only that if we are to be comparatively scientific about the nature of the ocean basins we had better drill some 20,000 m of basalts in suitably distributed DSDP holes. Only then could there be a geological dialogue of substance with respect to some of the matters indicated here.

reviews

THE discovery of X rays by Röntgen in 1895 gave rise to considerable speculation as to whether this radiation was corpuscular, like electrons, or undulatory, like light. As the experimental evidence grew so it became apparent that, like light, X rays must be a form of electromagnetic radiation; Barkla demonstrated that X rays could be polarised and in accordance with J. J. Thomson's theory, this was taken as clear evidence for their being electromagnetic waves; this conclusion was reinforced some years later by Friedrich, Knipping and Laue, who showed that they could be diffracted. Nevertheless there was one property of light which eluded a satisfactory explanation on this wave basis and that was the photoelectric effect. The only simple explanation for this phenomenon was given in 1905 by Einstein, who published his well-known paper on the light quantum interpretation of the photoelectric effect and derived his famous relation $eV = h\nu$. Not much notice was taken of Einstein's contribution and the view was firmly held by the majority of physicists that light and X rays were electromagnetic waves and this therefore excluded them from possessing particle properties. Even as late as 1916 Millikan, in the paper reporting his experiments on the photoelectric effect which exactly confirmed the Einstein relation, commented: "Yet the semicorpuscular theory by which Einstein arrived at his equation seems at present to be wholly untenable". This relationship was accepted as convenient and reliable and it was presumed that it would ultimately prove explicable on electromagnetic theory.

It was at this stage that A. H. Compton came on to the scene. He had started his research under O. W. Richardson at Princeton in 1914 on X-ray diffraction and, after some abortive experiments to look for magnetic scattering of X rays, commenced his experiments on the spectrum of the scattered radiation. These were absorption experiments and they showed that, together with the radiation of unaltered wavelength, there also seemed to be softer radiation present. Barkla had observed this radiation

Waves or particles?

Photo: Stephen Deutch, Courtesy AIP Niels Bohr Library

A. H. Compton at work

and interpreted it as fluorescent radiation characteristic of the scatterer—but longer in wavelength than those lines which can be understood by the Bohr model—and named it J radiation. Compton, adhering strongly to electromagnetic theory, chose to interpret the changed absorption coefficient not as a change in wavelength, but as being due to the size and shape of the electron: by assuming that it was a rather large object and of ring shape, he found that he could account for the reduced absorption coefficient in the conditions of his experiment. After visiting Cambridge in 1919, where Rutherford viewed his large electron with some scepticism, he returned to the US and attacked the scattering problem again, this time using a Bragg spectrometer as a monochromator of the incident X rays. He then found an explanation for the softening of the X rays in terms of Doppler displacement of the radiation from the moving electron, which had received momentum from the incident X rays. He was still, however, unable to account satisfactorily for all the features of scattering and it was only at this stage in October 1922 that he found that a corpuscular interpretation would account fully for all his observations. Quite quickly, most physicists accepted this interpretation of

his convincing experiments and thus accepted the particle nature of electromagnetic radiation. Thus, some 17 years after Einstein's original paper on the photoelectric effect, the scientific community recognised the fact that light and X rays each possessed both wave and particle characteristics.

In this book* Dr Stuewer, an historian of science, traces the ideas and background to Compton's experiments which were to prove important in the development of wave-mechanics. The author, using material drawn from published papers and letters, guides the reader through much of the history of the particle-wave duality. It is liberally referenced and sprinkled with detailed theoretical arguments, and the tenacity with which physicists held to the classical electromagnetic theory emerges very clearly in this book. This piece of physics history will be primarily of interest to physics graduates and, although lacking the gossipy and humorous touches of biography, it nevertheless provides a vivid, enjoyable and definitive account of one of the crucial steps in the establishment of quantum mechanics. It is an unusual work and should have a place in the library of the physicist who is interested in more than the bare bones of his subject.

M. A. Grace

**The Compton Effect: Turning point in Physics*. By Roger H. Stuewer. Pp. xii+367. (Science History: New York, April 1975.) n.p.

Biochemical and biophysical aspects of photosynthesis

Bioenergetics of Photosynthesis. (Cell Biology: A Series of Monographs.) Edited by Govindjee. Pp. xiv+698. (Academic: New York and London, April 1975.) £20.65.

OFTEN books born of long gestation periods are disappointing when they finally arrive. That is definitely not the case with this well edited volume, which should have a very useful life in the library and on the desk.

The book comprises 12 chapters by selected authors who cover the general biochemical and biophysical aspects of photosynthesis in plant and (to a lesser extent) bacterial systems. The way in which this is related to bioenergetic conversion is dealt with from several points of view: membrane structure related to pigments and energy conversion; chloroplast structure; the primary events of photosynthesis including luminescence and fluorescence; oxygen evolution; electron transport; phosphorylation; and ion movements. Each chapter has been externally reviewed and the editor has inserted useful cross references. This, combined with the extensive references, the list of abbreviations and the tables, ensure that each chapter, though complete in itself, is also relevant to other chapters.

The subject index and author index are excellent—necessarily so in a book which claims to “serve as a reference source for researchers but also as an introductory work for graduate students”—and, consequently, the book is more useful than volumes of proceedings and monographs which lack such indexes. It is a pity that more publishers do not insist on the inclusion of extensive indexes even though the resulting books may be more expensive than otherwise—in the long run readers would find the extra expense well worthwhile.

Since the practical use of photosynthesis based on both the improvement of its natural efficiency and the construction of artificial systems are so in vogue now (for food and/or energy) it is a pity that a chapter on this important topic was not included.

An understanding of the biochemical and biophysical mechanisms of photosynthesis seems crucial to its future exploitation and this is where this book will provide the source of background information for present and future investigations—whether scientific, administrative or commercial. **D. O. Hall**

Magnetic oxides

Magnetic Oxides. Edited by D. J. Craik. Part 1: Pp. xxi+482. Part 2: Pp. xix+483-798. (Wiley: London and New York, 1975.) £15.00 each.

THESE two volumes cover various aspects of the theory, properties and uses of magnetic oxides. The 13 chapters are written by 20 authors and cover an extremely wide range, from the practical arts of crystal growing to the theoretical intricacies of crystal fields and exchange. The versatility of magnetic oxides as recording media is also well covered in chapters ranging from the recently utilised bubble domains to the recording over geological times of past terrestrial magnetic fields in the oxides which occur naturally in rocks. There are also chapters on such topics as anisotropy, magnetostriction, optical properties, electrical properties, domains and microwave resonance. Experimental techniques such as neutron diffraction and nuclear magnetic resonance are, of necessity, mentioned here and there but are not discussed fully.

The question of units in a multiple

author book on magnetism is bound to present an initial problem, at least, and it has been solved in this case using e.m.u. throughout, in line with most of the literature. It is, perhaps, not surprising in view of the wide field that the treatment of many of the topics is not detailed enough to be followed by the reader without frequent recourse to references, and in that respect the book tends to be a rather thorough review of the current state of knowledge. That is, however, the major strength of the work and each chapter is well provided with a comprehensive list of references, there being something like 1,700 in the whole book.

Although the individual chapters are to a large extent independent of each other, the work as a whole is well integrated by frequent cross-referencing where interaction of subject matter does occur. The book is perhaps most likely to appeal to the specialist who wishes to extend his knowledge of other aspects of magnetic oxides, and for that purpose it is of considerable value in view of its logical presentation and comprehensive referencing.

A. Stephenson

Kets, bras and boson variables

Spinors in Hilbert Space. By P. A. M. Dirac. Pp. vi+91. (Plenum: New York and London, 1974.) \$14.50.

ON reading this volume, I had at once an impression of *déjà vu*, hearing again the logical, elegant and irresistible exposition so well known to us from Professor Dirac's classic work *The Principles of Quantum Mechanics*. This book differs from the latter, however, in being primarily mathematical in character. Its relevance to the physics of the real world is mentioned in only a few of its 35 sections. The book is based on a series of lectures which the author gave at the University of Miami in 1969. Although self-contained, it is not really intended for the beginner; for example, familiarity with the notion of a spinor and its properties and uses is very much taken for granted, although it is true that four lines in Section 2 do give a complete characterisation for a spinor quantity.

Dirac begins by developing the theory of vectors and operators in a real Hilbert space with $2N$ dimensions, in which there exists the concept of perpendicularity (as opposed to orthogonality, which concept also exists). He then introduces the operation of rotation and distinguishes spinors from tensors by the reversal of sign experienced by the former for a complete rotation. In this space, the vectors, termed kets, and their duals, termed bras, are the most elementary spinors, and Dirac confines his attention to them, since more complicated spinors can be constructed from them by multi-

plications, as done by van der Waerden in his lectures on spinors some decades ago. Their possible application to physical problems is not discussed in detail here, although Dirac does comment briefly about this at several points in the lectures, identifying, for example, the operators for the creation and destruction of fermions.

Dirac then approaches the case of special interest for him, the case of a Hilbert space with an infinite number of dimensions, by taking the limit $N \rightarrow \infty$. For this, the operators of interest are those whose matrix is bounded, so that the operations of multiplication and division are defined for them. This limit leads Dirac to a new class of operators, which do not commute with each other nor obey the associative law of multiplication. He terms these as ‘boson variables’ and they come in two types, identified by Dirac as creation and destruction operators. In the closing section, Dirac emphasises that these boson variables appear automatically in infinite-dimensional theories which start with only fermion variables, provided that the latter are infinite in number. Dirac observes, “There must be such boson operators connected with electrons. Their physical presence is a subject for further investigation. They have a negative energy...”

This book is very much for the specialist, and one may expect it to have much value and influence in suggesting new extensions from the physical theories which we now know. We must note, however, that this little book costs 15 cents per page, which, even given the circumstances, does seem unnecessarily high.

R. H. Dalitz

NEW FROM ADDISON-WESLEY

ADVANCED BOOK PROGRAM

MALCOLM P. STEVENS, *University of Hartford***POLYMER CHEMISTRY: An Introduction**

Provides an updated introduction to the field of polymer chemistry for the graduate or advanced undergraduate student. The major part of the book emphasizes the organic chemistry of vinyl and nonvinyl polymers, including modern concepts of reaction mechanism and stereochemistry; however, there is sufficient introductory material relating to polymer characterization, structure-property relationships, and polymer processing, to give a broad overview of the field. The book is divided into three parts, each part emphasizing a particular area of organic polymer chemistry. Each part also covers new developments and recent advances in its specific area. More chemists work in the field of polymers than in any other single area of chemistry, yet the subject is too often ignored in undergraduate or graduate curricula. "Polymer Chemistry" is designed to help meet this need as well as to serve as a reference source for the practicing research chemist.

Contents: INTRODUCTION TO POLYMERS: Basic Principles. Molecular Weight. Chemical Structure and Polymer Properties. Evaluation, Characterization, and Analysis of Polymers. VINYL POLYMERS: Free Radical Vinyl Polymerization. Ionic Vinyl Polymerization. Vinyl Polymerization with Complex Coordination Catalysts. Reactions of Vinyl Polymers. NONVINYL POLYMERS: Polyethers, Polysulfides, and Related Polymers. Polyesters. Polyamides and Related Polymers. Phenol-, Urea-, and Melamine-Formaldehyde Resins. Inorganic-Organic Polymers. Miscellaneous Organic Polymers. Natural Polymers. Appendix. Author and Subject Indexes.

1975, xvi, 457 pp., hardbound, £13.75
paperbound, £9.65

LAWRENCE E. MURR, *New Mexico Institute of Mining and Technology***INTERFACIAL PHENOMENA in METALS and ALLOYS**

Reasonably complete, extensive, up-to-date treatment of structure and properties of surfaces and internal interfaces such as grain boundaries in metals and alloys. Contains extensive tables of experimental measurements of interfacial energies.

From the Foreword by Morris Cohen: "Interfaces, both external and internal, constitute an integral part of the structure of materials, and so they enter directly into the structure/property/performance linkage which forms the central theme of materials science and engineering. These 'boundary aspects' of bulk materials, because of their relatively discontinuous character, are not only difficult to study and elucidate, but they can also exert major influence on the behavior of materials and, hence, dominate their utility in many applications. Interfaces are often regarded as two-dimensional imperfections in materials, along with the linear-defect dislocations and the point-defect vacancies and interstitialcies, but interfaces play an even deeper and more general role in nature's processes."

"Relatively powerful tools have now become available for probing the structure and behavior of interfaces, including field-ion and atom-probe microscopy, Auger spectroscopy, high- and low-energy electron diffraction, scanning and transmission electron microscopy, quantitative stereology, high-vacuum and thin-film technologies."

Contents: Thermodynamics of Solid Interfaces. Interfacial Equilibria. Interfacial Free Energy. Structure of Interfaces. Properties of Interfaces. Author Index. Subject Index.

1975, xiv, 376 pp., illus., hardbound, £13.50
paperbound, £9.20

E. GILEADI, E. KIROWA-EISNER, and J. PENCINER, *Tel-Aviv University***INTERFACIAL ELECTROCHEMISTRY: An Experimental Approach**

With the renewed interest in electrochemical energy conversion since the end of 1973, a scientist entering the field could choose from a sizable bookshelf of texts on the theoretical aspects of interfacial electrochemistry. Yet there was no book which could help the newcomer to the field to acquaint himself with the various techniques most commonly employed in the study of electrode kinetics. This book was written to bridge the gap. It is meant both as a standard text for advanced graduate courses in electrochemistry and as a self-teaching aid for learning new techniques in electrochemistry.

Contents: SOME THEORETICAL CONSIDERATIONS. The Structure of the Ionic Double Layer. Potential Differences Across Interphases. Polarizable and Nonpolarizable Interphases. Electrocapillary Thermodynamics. Electrode Kinetics. Evaluation of Kinetic Parameters. Adsorption of Intermediates. The Adsorption Pseudocapacity. Adsorption of Neutral Species. Analysis of Reactions Occurring Under Mixed Activation and Diffusion Control. Fundamentals of Corrosion. Batteries and Fuel Cells. Fundamentals of Electroplating. EXPERIMENTS. Experiments in Electronics Related to Electrochemistry. Reference Electrodes. Double Layer Measurements. Structure of the Ionic Double Layer and Electrode Processes. Kinetics of Hydrogen-Evolution Radiation on Solid Electrodes. The Rotating-Disc Electrode. Reaction Order Studies. Determination of Kinetic Parameters by Galvanostatic and Potentiostatic Transients. Cyclic Voltammetry. Voltammetry at Controlled Current and at Controlled Potential. Adsorption of Oxygen and Hydrogen on Noble-Metal Electrodes. Electrosorption. Absorption of Hydrogen in Palladium and Diffusion Through It. Kinetic Studies of the $\text{Ni}(\text{OH})_2/\text{NiOOH}$ System. Index.

1975, xii, 522 pp., illus., hardbound, £10.75
paperbound, £7.45

C. PIRON, *University of Geneva***FOUNDATIONS OF QUANTUM PHYSICS**

This book gives a unified formulation of "quantum" physics, avoiding the commonly accepted division between classical and quantum mechanics. The formalism presented is obtained by taking seriously Einstein's point of view and describing a physical system in terms of "elements of reality."

Contents: The Classical Case. The Quantum Case. Realizations. Measurements and Probabilities. Applications. Index. The first chapter describes classical mechanics from this point of view, before introducing a language which is adequate for the purpose of this book. This new language is developed and explained in detail in Chapter 2. Chapter 3 is essentially of a technical nature: it justifies the introduction of Hilbert space as a natural realization of the more abstract structures discussed in the first two chapters. The fourth chapter exposes the theory of measurement and gives the "calculus" of probability which is characteristic to quantal systems. Chapter 5 discusses various applications, including those of different models of Galilean particles.

1975, about 150 pp., hardbound, £9.65
paperbound, £4.70

STRUCTURAL STABILITY AND MORPHOGENESIS

An Outline of A General Theory of Models

Translated by D. H. Fowler from the French edition, updated by the author, with Forewords to the original French and updated English editions by C. H. Waddington

Contents: Form and Structural Stability. Structural Stability in Mathematics. Kinematic of Forms; Catastrophes Elementary Catastrophes on R^4 Associated with Conflicts of Regimes General Morphology. The Dynamic of Forms. Biology and Topology. Local Models in Embryology. Global Models for a Living Being (Metazoa). Models in Ultrastructure. The Basic Problems of Biology. From Animal to Man, Thought and Language. Mathematical Summary. Index.

Review of original French edition: "It is impossible to give a brief description of the intellectual impact of this book. In one sense the only book with which it can be compared is Newton's *Principia*. Both lay out a new conceptual framework for the understanding of nature, and equally both go on to unbounded speculation. From Newton's book, as Truesdell says, 'our forebears learned how to use the concept of force given *a priori*', and there can be no doubt that from Thom's will come an elaboration which will allow our children to use more precisely the concept of catastrophe that he introduces. Almost all of the speculation in the *Principia* has turned out to be hopelessly wrong, though it would be hard to say to what extent this prevented its being useful at the time. So the criterion for Thom's speculative applications must come from their stimulating character, without trying to prejudice their correctness." — *The Times Higher Education Supplement*

Introduction to AXIOMATIC QUANTUM FIELD THEORY

Authorized translation from the Russian by Stephen A. Fulling and Ludmila G. Popova

The book provides a systematic, self-contained, and modern exposition of axiomatic quantum field theory. It does not require much preliminary knowledge of either mathematics or quantum field theory and leads the reader to the present-day frontiers of the subject. It includes some original methods and results to which the authors have made substantial contributions. A significant amount of this material has been specially written for the English edition.

Contents: Introduction. Elements of Functional Analysis and the Theory of Distributions. The General Principles of Relativistic Quantum Theory. Local Quantum Fields and Wightman Functions. Asymptotic Conditions and Scattering Theory. The Axiomatic Theory of the S-Matrix. Consequences of the Relativistic Invariance of Quantum Theory: TCP, Spin and Statistics, Haag's Theorem. The Quantum Theory of Local Observables and Progress in Constructive Quantum Field Theory (Review of Results). Bibliography. Author Index. Subject Index.

1975, xxviii, 708 pp., hardbound, £17 90

BIOLOGICAL TRANSPORT Second Edition, completely revised, reset, enlarged

An up-to-date presentation of central aspects of molecular transport across biological membranes is now available in this completely revised edition. The parallel subject of group translocation is discussed. Here is a critical guide to the original literature for use by the advanced student of bioscience.

Contents: A Survey of the Scope of the Problem of Transport. Membrane Composition and Structure. Thermodynamic Aspects of Transport. Kinetics in Transport. Effect of Solute Structure on Transport. Genetic Approaches to the Study of Transport Systems by Dale L. Oxender. Binding Proteins and Transport. Group Translocation. Structurally Bound Adenosinetriphosphate-Phosphohydrolase of the Animal Cell by Gunnar Ronquist. Transport in the Mitochondrion. On Mechanism and Energy Transfer in Transport: Some Provisional Models. Effects of Transport on Distribution of Ions and Metabolite Transport. Development and Regulation. Some Practical Considerations of Techniques in Transport Studies. Appendices: Terminological Considerations. Corrections for Nonsaturable Migration. Illustration of Preparation of Solutions. References. Author Index. Subject Index.

The Principles of Human Biochemical Genetics

Second Revised and Enlarged Edition

by **HARRY HARRIS**, Galton Laboratory, University College, London.

Frontiers of Biology, Vol. 19*

1975. 488 pages. Clothbound Price: US \$ 49.95/Dfl. 120.00. ISBN 0-7204-7119-2
Paperback Price: US \$ 20.50/Dfl. 49.00. ISBN 0-7204-4504-3

"...intended not only for those specifically studying human genetics but also for biochemists, biologists and medical men. It is exactly that circle of readers which will find not only information but also inspiration in this book."

Nature

"This book is written with great clarity by our leading authority in the subject."

Endeavour

"...this type of book is a windfall."

BioScience

The above reviews indicate some of the enthusiasm with which the first edition of this book was received in 1970. It went on to become an adopted text by many graduate departments in the United States. The new edition, which encompasses the changes occurring in this large field during the past five years, is undoubtedly one of the most important second editions published on human biochemical genetics. Professor Harris has gathered together and collated extensive information in the field which previously was scattered in numerous journals; the result is a well coordinated text presenting most aspects connected with this area of research. The volume presents a general account of the field while stressing the principle concepts underlying modern research. The net outcome is a clear and well documented account of how inherited diseases and other abnormalities due to inborn biochemical diversity can now be understood as an inherent aspect of the biochemical make-up of human beings.

CONTENTS: Gene mutations and single amino-acid substitutions. One gene - one polypeptide chain. Duplications, deletions, unequal crossovers, chain elongations and other rearrangements. Gene mutations affecting rates of protein synthesis. Quantitative and qualitative variation of enzymes. The inborn errors of metabolism. The blood group substances. Enzyme and protein diversity in human populations. Gene mutations and inherited disease. Appendix 1. Disorders due to specific enzyme deficiencies (inborn errors of metabolism). Appendix 2. Enzyme and protein polymorphisms. References. Subject index.

Group theory and electronic states

Symmetry of Many-Electron Systems. (Physical Chemistry: A Series of Monographs, vol. 34.) By I. G. Kaplan. Translated by J. Gerratt. Pp. xii+370. (Academic: New York and London, February 1975.) \$34.50; £16.55.

GROUP theory has been used for many years in the quantum mechanical analysis of many particle systems. This monograph deals only with applications to many electron systems, specifically atoms and molecules, the physical properties of which reflect both the symmetry with respect to the permutation of the identical particles of which they are composed and the symmetry of the potential field formed by the nuclei within which these particles move. Other fields of application are ignored.

The book opens with an account of some of the main facts of group representation theory presented as a tool for the chemist, which omits many of the proofs and derivations. The permutation group is singled out for detailed study, an understanding of Young tableaux and Young operators being essential in later chapters. Linear groups of transformations (including the three-dimensional rotation group), point symmetry groups,

and the construction and uses of tensor representations and irreducible tensor operators are all described briefly.

The rest of the book is devoted mainly to the classification and calculation of electronic states of atoms and molecules. Considerable use is made of fractional parentage expansions, which are worked out in detail for the atomic case in $j-j$ coupling and then generalised to handle the non-vector-coupled states that are of importance in molecules. They allow one to construct matrices of one and two-electron operators for an arbitrary molecular system, and in particular to deduce the form of the Hamiltonian matrix. The book ends with an account, specially prepared for the English edition, of Hartree-Fock theory in an orthonormal orbital basis, a survey of methods of treating electron correlation and derivations of self consistent field equations for configurations of spin-degenerate states and for a configuration of non-orthogonal orbitals in the method of 'different orbitals for different spins'.

The calculation of a molecular structure involves a number of successive stages: mathematical methods are first of all needed to formulate appropriate equations for the problem; a numerical method must be devised to solve the equations as economically as possible; the solution must be performed to give

numbers; finally the numbers must be interpreted to give insight into the physicochemical problem under study if possible. The laborious and expensive nature of these calculations reflects the fact that none of these stages are trivial; however, Kaplan only considers the first of them. The group theoretical techniques that he describes are immensely powerful, but are sometimes handled in an uncritical way, as in the use of Young tableaux in the description of the Heitler-London calculation for H_2 . Several types of calculation are described, some of which have not yet been implemented in practice, without any discussion of their advantages or disadvantages, consideration of alternative methods, or presentation of numerical results. This lack of critical discussion means that the book is likely to be of most use to the experienced theoretician who wishes to understand how to exploit the techniques in his own work. The novice would find it tough going and would also be put off by the prohibitively high price.

The translation has been carefully done and I only detected a small number of relatively trivial errors. The original Russian text dates from 1969; consequently, the majority of the references are to literature from earlier years though a handful are of more recent origin.

I. P. Grant

Integrated biology

The Peripheral Arterial Chemoreceptors. (Proceedings of an International Workshop.) Edited by M. J. Purves. Pp. xiii+492. (Cambridge University Press: London, June 1975.) £14.00; \$39.50.

THE carotid body seems to have been the subject of more papers (per weight of tissue) than any other vertebrate sense organ; yet it is probably the least understood in terms of its functional morphology. In recent years this situation has been compounded by the publication of conflicting data, which was the main reason for convening a work session at Bristol in 1973. The present book is the outcome of this meeting.

Unfortunately, the editor gives no indication in the Preface or elsewhere in the book as to what the major unresolved problems and areas of contention are. Furthermore, there is no epilogue to indicate whether, or to what degree, the symposium was successful in resolving any of the controversial areas of research. The reader is therefore left with no alternative but to read the entire book to ascertain where the problem areas lie. Not that this is an unrewarding enterprise: all the articles are well written and of a very high standard.

Perhaps the greatest value in this book lies in the discussions at the end of each

paper, for it is among these pages that the reader is made aware not only of the specific problems in carotid-body research, but also of the subjective nature of the so-called exactness of the scientific method. For example, it is apparent that recognition of nerve processes in electron micrographs is achieved at least as much by intuitive as by objective criteria (page 39).

The subject matter ranges from ultrastructural studies, through neuropharmacological, neurophysiological and metabolic aspects of the carotid body sense organ, to circulatory and respiratory chemoreflexes in the whole animal. In general, the presentation is excellent, which is probably why the few minor editorial faults in the book are so irritating. The electron micrographs are displaced from both text and the legends so that the reader has to keep track of three pages simultaneously if he is effectively to follow the anatomical contributions. Some of the electro-neurograms are poorly reproduced and there are a number of mistakes in the reference lists.

Nevertheless, these faults do not detract from the overall excellence of this book, which can be recommended unreservedly not only to mammalian physiologists, but to all who are interested in an integrated approach to problems in biology. M. P. Osborne and P. J. Butler

Plasma scattering

Plasma Scattering of Electromagnetic Radiation. John Sheffield. Pp. xii+305. (Academic: New York and London, January 1975.) \$29.00; £13.90.

IN this book John Sheffield covers those aspects of the Thomson scattering of laser radiation by a plasma that are relevant to diagnostic applications. The technique, perhaps the most powerful and elegant to have emerged from work on controlled fusion and other laboratory plasmas, presents particular experimental difficulties in view of the very low ratio of scattered to incident light ($<10^{-12}$ – 10^{-14}). In appropriate circumstances, however, it is unique in the direct relationship between observed quantities and basic parameters such as electron velocity distributions and number densities, and in other cases it provides more complex information. Consequently, various aspects have already formed the subject of many reviews.

Problems arise in devoting an entire book to this topic because of the difficult

choice that must be made between presenting a detailed re-exposition of plasma kinetic theory or assuming a background knowledge and adopting an approach more typical, perhaps, of a review article. By and large John Sheffield copes well with this balance. Though highly specialised, the book will clearly be of considerable use to anyone involved in Thomson scattering measurements, as much for physical explanation and theoretical development as for a reference source. Within the confines of the subject the scope is quite wide, with, for example, chapters covering experimental constraints and optical techniques as equally as, say, the theory of scattering from unstable plasmas. The biggest limitation is that the particular theoretical approach chosen is perhaps not the most suited for comparison with scattering processes operating in systems other than plasmas, so that the book is necessarily limited to a very specialised field within plasma physics. Within that constraint, however, I think the book will prove worthwhile and useful. **D.D. Burgess**

Animal development

Practical Studies of Animal Development. By F. S. Billett and A. E. Wild. Pp. xi+251+6 plates. (Chapman and Hall: London, 1975.) £4.80.

Cellular Interactions in Animal Development. By Elizabeth M. Deuchar. Pp. x+298. (Chapman and Hall: London, 1975.) £6.50.

THERE are several good laboratory manuals available for classes in developmental biology. None is, or could be, comprehensive in the sense of dealing with the provenance and manipulation of all the major developmental systems. Each is of most value to teachers not themselves greatly experienced with the material described. *Practical Studies of Animal Development* by Billett and Wild should encourage enterprising teachers of this kind to attempt new laboratory experiments with their classes. The book provides guidance for work with an unusually wide range of animals—echinoids, ascidians, gastropods, annelids, nematodes, insects, teleosts, amphibians, birds and mammals. The exercises are set in the context of their scientific significance, so the book is not just a collection of recipes. Their selection could not suit everyone, but few teachers of developmental biology will fail to find useful matter in this book. In a second edition it might be worth adding a separate section on organ and tissue culture techniques, giving guidance on the nature and source of some of the materials mentioned (for example, MS 222).

We have had for some time in Ebert and Sussex's *Interacting Systems in Development* an admirable introduction to processes which must necessarily play a big part in any epigenetic event. Deuchar, with her *Cellular Interactions in Animal Development*, now offers a more extended, and more detailed, treatment both of the best known and of many less celebrated cases of cell-interactions in animals. There is virtue in reminding students that the more famous examples form but the tip of an iceberg, and I believe that this book will be successful in exciting student interest not just in ideas, but in the systems on which they can be tested. Not many developmentalists, could hope to survey so wide a range of phenomena as Deuchar does, and although she is still only introducing the reader to the problems she deals with, the end result is a very substantial coverage of those parts of developmental biology that are not 'molecular' or 'genetic'.

Her stories are open ended and she indicates areas of doubt with scrupulous care. I could, indeed, have wished that she had given a more forceful statement of her own views in some cases. It wouldn't matter if some later turned out to be wrong. **D. R. Newth**

Allergic diseases

Immunological Aspects of Allergy and Allergic Diseases. Edited by E. Rajka and S. Korossy. Volume 1, Pp. x+456. Volume 2, Pp. xii+457-759. (Plenum: London and New York; Akademiai Kiado: Budapest, 1974.) \$42 each.

THE unprecedented rate of expansion in immunology during the late sixties and the seventies has not been conducive to the compilation of textbooks. Their place has been taken by numerous excellent monographs of an advanced nature while medical students have been catered for by a number of introductory booklets to modern immunology, mostly of exceptionally high standard. The revolutionary new concepts, however, particularly in this field of cellular immunology, have now become consolidated and these two volumes represent one of the first attempts to contain the avalanche of recent information under one roof. The authors are an almost exclusively Hungarian team and have largely succeeded in producing a reasonably up-to-date handbook of immunology for clinicians, with the special interest of the editors-in-chief in atopic allergy largely underplayed.

The first volume deals with the more theoretical basic aspects of modern thought on immune induction and unresponsiveness, whereas the second discusses diagnostic procedures, transplantation and tumour immunology, with two further volumes of a more clinical nature yet to come. Each chapter is generously supplied with references up to and including 1973.

The occasionally quaint phraseology may charm or irritate, but the text is usually clear and controversial matter well argued. In spite of a chapter devoted to terminological aspects, however, confusion sometimes arises from old and new terms being used interchangeably by some authors, and a much needed glossary is lacking.

On page 349 now hardly relevant theories on reagin structure are given a reference to a much later factual paper containing first numerical data on reagin persistence in skin and showing that reagins do not belong to any then known Ig class, but can be assayed by passive sensitisation of chopped lung, data later ignored in their proper context. There is a somewhat irrelevant though well-written chapter on non-Ig serum proteins. In a detailed chapter on the Shwartzman phenomenon, conclusions about its non-immunological nature are reiterated, ignoring recent evidence on massive complement activation as the trigger mechanism. Immunological aspects of nematode infections are not covered in spite of their recent basic interest as regards reagin formation. And although autoimmunity is discussed at length, modern ideas on the bypassing of antigen-specific T-cell cooperation as a fundamental and for the first time integrated mechanism are ignored. The subject index is deplorably incomplete and there is no author index.

Publication of this book coincides with that of an excellent third edition of an established English textbook covering similar ground at roughly half the price for twice the number of pages. **R. Augustin**

obituary

Lancelot Hogben, FRS, populariser of science and author of *Mathematics for the Million*, died on August 22 at Wrexham Hospital in North Wales. He was four months short of his 80th birthday.

Hogben was born in Southsea of aggressively devout Calvinistic parents, educated in the public schools of Portsmouth and was one of the first batch of County Scholarship boys to enter Trinity College, Cambridge, where he studied zoology. The condescension with which he says he was met left deep and ineradicable mental scars. There, he met and was deeply impressed by the philosopher Bertrand Russell. They remained friends until Russell's death. The influence of Russell—in addition to playing a determining part in Hogben's decision to go to gaol as a conscientious objector in the First World War, although possessed of exemption papers—provides the thread of continuity that ran through the astonishingly wide range of subjects to which Hogben made major contributions. He took nothing on trust, and he explored the fundamentals of each discipline before he expounded it. It was this insistence on knowing what he called the "logical credentials" of each subject that made him—like J. B. S. Haldane—one of the very great "popularisers" of science in the tradition of Clerk Maxwell and Michael Faraday.

After graduation from Cambridge he was lecturer in zoology at Imperial College, London (1919–22); assistant director of the Animal Breeding Research Station, Edinburgh (1923); lecturer in experimental physiology, Edinburgh (1923–25), assistant professor of zoology, McGill (1925–27); professor of zoology, Capetown (1927–30); professor of social biology, London

School of Economics (1930–37); Regius Professor of Natural History, Aberdeen (1937–41); Mason Professor of Zoology, Birmingham (1941–47; during much of this time he was seconded as Colonel to the Directorate of Biological Research, later called Directorate of Medical Statistics, at the War Office, to work with his onetime mentor, and friend, the late Professor F. A. E. Crew); Professor of Medical Statistics, Birmingham (1947–61); Honorary Fellow in Linguistics, Birmingham (1961–63); Vice-Chancellor and Principal, University of Guyana (1963–65).

Besides numerous articles in scientific and medical journals (many of fundamental importance) he wrote a wide range of books ranging from textbooks on zoology through the immensely influential *Primers for the Age of Plenty*, of which *Mathematics for the Million* is perhaps the best known, books on language and linguistics, including *Interglossa* (a blueprint for an international language) and *Astroglossa* (for interplanetary communication) to a hilarious and educative tale, all in words of one syllable, called *Whales for the Welsh*. His two Conway Memorial Lectures, "The Retreat from Reason" and "Authoritarianism and Science" deserve re-reading in the present scientific climate. Hogben was a true polymath. He was honoured with the Keith Prize and Gold Medal of the Royal Society of Edinburgh, a Croonian Lectureship.

That is just the bare bones of what Hogben had achieved. What of Hogben the man, funster, punster, controversialist, socialist, enemy, teacher and friend? That Hogben could be awkward, irascible, impossible and sometimes unreasonable seems, from the frequency with which it has been recorded, to be incontrovertible. He did, however, keep these aspects of his

character in the main for those whom he considered were, in virtue of their position, of equal or superior status. He castigated unmercifully what he regarded as meretricious or intellectually dishonest, but he had patience with the obtuse if he thought they showed a genuine desire to comprehend what he had to impart. He was not very good at what he delighted to stigmatise as "oral intercourse", preferring the written word. Possibly this was because his own speech was "lacunary"—terse and pithy but with whole paragraphs elided—and it took some time to become proficient in interpreting this.

He had an enormously stimulating influence on young scientists, both in his own Department and in others. Birmingham University certainly owed much to him. He would also defend the student interest against illiberal oppression by the dinosauric hierarchy. One instance of this happened at a meeting of the Senate at the University of Birmingham towards the end of the war period. There was a move afoot to cut down the autonomy of the Students' Union, ostensibly because a used contraceptive had been in a fire bucket after a dance. One professor, who for years had almost ruled the Senate, said that, speaking as a father, he was horrified to think that he had sent his daughter to a University where such things were used. Hogben replied that, speaking as a father and a grandfather, he would have been horrified if he thought that he had not. Report has it that after a moment's stunned silence the Senate suddenly dissolved into laughter and the whole episode was seen for what it really was. The next day the President of the Students' Union came to thank Lancelot for what he had done, and the long tyranny of the fossilised one was for ever broken.

announcements

Award

Maurice Strong, executive director of the United Nations Environment Programme, is to receive the **Audubon Medal** from the **National Audubon Society** for his role in making the environment an international concern.

Appointments

Professor Michael Sela is to be the next president of the Weizmann Institute of Science.

The University of Adelaide has appointed **Professor Colin J. Driscoll** to the Waite Chair of Agronomy in the Waite Agricultural Research Institute.

Miscellaneous

The second edition of *Collected Tentative Rules and Recommendations of the IUPAC-IUB Commission on Biochemical Nomenclature* is now available for distribution. Copies can be obtained from:—The American Society of Biological Chemists, Inc., 9650 Rockville Pike, Bethesda, Maryland 20014.

nature

October 2, 1975

Dear Sir...

Thank you for your application to the Astronomical Research Council for a grant to support the project "Determination of past sunspot numbers from mediaeval records of the swede harvest". The council unfortunately felt that this work was predominantly within the domain of the Vegetable Research Council to whom you are recommended to apply.

Thank you for your application to the Vegetable Research Council for a grant to support the project "A study of the past swede harvests and extraterrestrial influences on them". Unfortunately, the council felt that this work was too interdisciplinary to come within its purview; it recommends you to try the Interdisciplinary Research Committee.

Thank you for your application to the Interdisciplinary Research Committee for a grant to support the project "Stellar magnetohydrodynamics, solar disturbances, atmospheric impacts and their meteorological consequences for agricultural productivity based on mediaeval records". Although the committee felt the research was timely, it feared it did not have enough promise in it. But have you tried one of the foundations—they can often support this sort of work?

Thank you for your application to the Doogood Foundation for a grant to support the project "Man's well-being improved by a better understanding of the influences on agricultural productivity". The foundation felt that the work, although showing great promise, could not yet be regarded as timely. Maybe there are some funds available in your own university.

Thank you for your application to the Miss Hygienia Philpott Fund, for support for your project "A search through mediaeval records within the university". It is true that Miss Philpott's Will did encourage research within the university archives but she added the rider "insofar as this may tend to increase the virtue and godliness of the scholars of the university". The trustees of her Will regrettably could not see such an outcome in this case; surely a government department would support such work?

Thank you for your application to the Ministry of Commerce for support for your project "Improving the balance of payments by a more profound knowledge of the forward market in swedes". We have several laboratories employing thousands of scientists; the project would be ideal to give them something to do, but we couldn't give support for an outsider to do it. Couldn't industry help?

Thank you for your application to the Giant Swede Corporation for support for your project "Better swedes

within the next eleven years". Unfortunately the people in our research laboratory are not too keen on ideas that they have not initiated themselves. Furthermore I should add that the amount of money the swede industry has available for research is very small. Might I recommend you try an organisation with more funds?

Thank you for your application to the Ministry of Defence to support the project "Historical variability in the swede harvest and problems of feeding armies, possible causes". Although it is true that we have substantial funds available for research, we are under growing pressure to demonstrate that this research is relevant to modern military methods. Might I suggest you reword your application appropriately and send it to the Ministry of Attack?

Thank you for your application to the Ministry of Attack to support a project "More effective thermonuclear weapons through better understanding of time-dependent thermonuclear processes in the Sun". Unfortunately the Minister is increasingly worried by the damage that students are causing to university laboratories at which military research is being done. Maybe you could disguise your work with a humanitarian purpose.

Thank you for your application to the Cancer Foundation to support a project "Do sunspots cause cancer directly or through swede harvest variability?" I'm afraid we found the proposal a little far-fetched. Maybe a private benefactor would help.

Thank you for your letter to the Twelfth Marquess of Cumberland requesting support for your project "Harvests were better in the olden times". Unfortunately His Grace is a trifle penurious these days what with swingeing taxation, and he writes from Bermuda to recommend that you follow his example of collecting money in small quantities from large numbers of people in return for some favour that you can bestow upon them.

It has been brought to the attention of the Director of Public Prosecutions that you together with some students were to be seen last Saturday dressed as swedes and offering the public a look through a telescope at the Sun in return for 10p to "support research". Since I do not find your name on the list of registered charities licensed to collect in the streets, I must warn you that any repetition of this offence will lead to prosecution. Besides, there are perfectly normal channels for obtaining money for research purposes; perhaps you are unaware of the government's handbook which lists them (alphabetically) as the Astronomical Research Council, . . .

... Your obedient servant

IN his first major statement on energy policy, President Ford last January declared that he firmly supports a massive expansion of the nuclear energy programme in the United States. Without such an expansion, he argued, there is little hope that the nation can free itself from its painful dependence on foreign sources of oil, and he announced that his Administration would strive to ensure that at least 200 nuclear power plants are generating electricity by 1985. That would represent almost a fourfold expansion, from the present 55 nuclear stations.

With such a strong verbal commitment from the President, backed by more than \$1,000 million in the present federal budget for a variety of nuclear energy programmes, it might be supposed that the nuclear industry is in the midst of a bonanza. But it isn't. Instead, it is under siege, and it is facing a very uncertain future.

It is caught up in a complex web of technical, regulatory and economic problems, under assault by articulate and resourceful critics, facing increasing scrutiny by the Congress, and unsure of its public support. In fact, the problems are so serious that earlier this year a government task force concluded that "the nation's nuclear power program is approaching a state of crisis", and it added that it "is not optimistic that in the restrictive environment in which the nuclear industry operates today . . . actions can be implemented quickly and completely enough to avoid significant restriction on the growth of fission energy use". The task force which made those statements consisted of some of the top officials in charge of the federal government's nuclear energy programme.

One of the most acute problems afflicting the nuclear industry is an economic one—the national economic recession has more than made its mark on the industry. New orders for reactors, which not very long ago were coming in thick and fast from electric utility companies, have slumped recently, and the utilities have also been forced to postpone or cancel scores of orders which they placed before the recession began to bite. The figures speak for themselves: in the 18 months which ended on June 30, firm orders were placed for only 34 reactors, 17 reactors ordered previously were cancelled, and construction of 167 others was postponed for periods ranging from six months to indefinitely.

On top of those acute—and possibly short term—economic woes, the industry finds itself operating in a new and, its supporters insist, more hostile political environment in Washington. The demise earlier this year of the Atomic Energy Commission (AEC) and its replacement by the Energy

The first fuel bundle at the Duane Arnold Energy Center is lowered into its slot in the nuclear reactor, February, 1974.

Nader, anti-nuclear leader.

Energy policy in the United States assumes that there will be a marked expansion of the nuclear power programme, with as many as 1,000 nuclear power stations in operation by the year 2000. But the nuclear industry is now experiencing some of the toughest political and economic challenges it has ever faced. In the first of three articles on U.S. nuclear policy, Colin Norman reports from Washington.

Research and Development Administration (ERDA) demolished the bureaucratic structure which nurtured the early growth of the nuclear power programme, leaving the industry devoid of a solid power base in the federal government to look after its interests. Nuclear energy is now just one of five divisions in ERDA, and it must compete directly with other technologies for its share of the energy research and development pie.

And the industry's political base in the Congress is also fast being eroded. Congress is just beginning to take a searching look at the nuclear power programme, and for the first time in nearly 30 years, the powerful Joint Committee on Atomic Energy, which has jealously guarded the interests of the nuclear programme, has been forced to yield some of its monopoly over atomic energy affairs. A subcommittee of the House Interior Committee, under the chairmanship of Representative Morris Udall—a declared candidate for the Presidency—has been conducting prolonged and well publicised hearings on some of the more controversial aspects of the nuclear power programme, and the Congressional Joint Economic Committee has also been delving into the tricky questions of nuclear energy finances. Moreover, the Joint Committee on Atomic Energy is itself an entirely different animal from what it was just a year ago; two of its longest serving, and most powerful, members have left Congress, and the committee has benefited from an influx of more sceptical members of Congress.

This altered political environment sprung up just as a number of controversial issues, which will fundamentally affect the future growth of the nuclear industry, are coming to a head at the national level. In the next few years, the federal government will have to decide the structure of the uranium enrichment industry, how to dispose of radioactive waste material, whether to allow plutonium produced by reactors to be recycled as reactor fuel, and whether a new generation of breeder reactors should be built.

But, although those issues affect the long term structure of the industry, a more direct challenge to present-day nuclear operations is beginning to emerge at the state and local level. For the past four or five years, applications to build nuclear power plants have been challenged by local environmentalist and anti-nuclear groups, intent chiefly on keeping nuclear power plants out of their neighbourhoods. The groups have operated, more or less in isolation, by fighting the nuclear industry on a case-by-case basis. But recently their activities have become more coordinated, and a loose coalition has formed with

with a charismatic and highly effective leader—Ralph Nader.

The political effect of the local anti-nuclear groups is already being felt. According to a survey carried out in May this year for the Atomic Industrial Forum (AIF), the nuclear industry's trade association, there are bills pending in virtually every state legislature in the country which would to some extent curb the growth of nuclear power at the local level. Though very few of the more restrictive measures stand any chance of being passed, the sheer volume of the legislation is causing some concern among nuclear advocates. But a new development is causing even more concern.

Earlier this year, a coalition of environmentalist groups in California gathered together more than the 313,000 signatures needed to call a state-wide referendum on nuclear power next year. The referendum, in the form of a proposition which will be placed on the ballot papers for the Presidential primary elections in June, is a cleverly worded resolution which would forbid nuclear plants from being built in California unless they meet stringent safety criteria, unless safe waste-disposal measures have been devised, and unless the public is fully insured against the consequences of nuclear accidents. Moreover, if existing power plants in California don't meet the standards (which at present they don't), the proposition states that they would have to be gradually phased out of operation over a period of several years.

Ed Koupal, a Californian who organised the petition, is quick to point out that the measure "is not against nuclear power, it is for nuclear safety", but the net effect of the proposition—if it is passed—would clearly be to impose a moratorium on nuclear power in California. Though its chances of being passed are generally considered to be slim, there are two strong factors working in its favour. First, the concept embodied in the proposition—that nuclear power should only be allowed if it can be shown to be safe—is easy to sell in an election campaign. And second, a new California state law drastically limits the length of a campaign and the amount of money that can be spent in a state-wide election, which means that the nuclear industry cannot launch a massive propaganda blitz to get the measure defeated.

California isn't the only state likely to hold a referendum on nuclear energy matters next year. A group of environmentalist organisations, loosely coordinated into a coalition called the Western Block, is trying to get resolutions similar to the California proposition placed on the ballot papers in the November Presidential elections in 16

other states.

In short, therefore, the nuclear energy industry finds itself facing some of the toughest political and economic problems it has encountered in its troubled history, while, at the same time, the conventional wisdom among energy planners in the federal government is that a massive expansion of the nuclear programme will be vital to meet growing energy demand.

The industry is gearing up to put its case across to Congress and the general public. The AIF, for example, is stepping up its public relations campaign; it has moved its headquarters from New York to Washington, doubled its budget to \$1.2 million a year, and is already sending out reams of paperwork to the news media. AIF officials say that they do not plan to do any direct lobbying because another industrial organisation has been set up for that purpose. Called the Nuclear Energy Council, it is headed by former Representative Craig Hosmer, who was the ranking Republican on the Joint Committee on Atomic Energy until he retired from Congress last year.

In several respects, the industry has a number of advantages over its critics in its bid for national attention. Not only is the AIF able to outspend the nuclear critics by almost an order of magnitude, but it is much better organised and has far greater resources to draw on. Moreover, it recently received a considerable boost from a public opinion poll, carried out by Louis Harris. The poll revealed that 69% of the public would approve an expansion of the nuclear power programme in the United States, while only 19% of the respondents declared themselves opposed to such a move.

The chief nuclear critics operating at the national level are Ralph Nader's organisation, the Union of Concerned Scientists (UCS) and the Natural Resources Defense Council (NRDC). The UCS has provided most of the technical backing for challenges to the safety of nuclear power plants, and its principal leaders are Henry Kendall, an MIT nuclear physicist, and Dan Ford, an economics graduate. The NRDC has been most active in attacking health standards associated with plutonium, safeguards against the theft of a weapons-grade nuclear material, and the government's arguments in support of the liquid metal fast breeder reactor programme (LMFBR). Tom Cochran, a nuclear physicist, Arthur Tamplin, a former AEC health physicist, and Gus Speth, a lawyer, form the basis of NRDC's nuclear attack force.

The debate on the desirability of nuclear power has, of course, been going on for several years, but its focus has shifted considerably. Early con-

cern about the health effects of the releases of small amounts of radioactivity from power plants, and worries about the environmental effects of thermal emissions, have greatly diminished—chiefly because the standards have been considerably tightened. The most controversial issues now are the safety of light water reactors, hazards associated with plutonium, the proliferation of nuclear weapons, and the difficulty of finding a safe method for disposing of highly radioactive reactor wastes. Those issues will ultimately have to be resolved by Congress.

Congress will have to make up its collective mind on the following matters.

Energy demand. An underlying feature of the entire nuclear energy debate is a fundamental divergence of opinion on energy policy. The nuclear critics, in short, argue that if stringent, mandatory energy conservation measures are applied, and if research and development on technologies for using solar energy are stepped up, the nuclear programme can be slowed down and there will be no need to develop the breeder reactor. The most forceful backing for that viewpoint was incorporated into the findings last year of the Ford Foundation's Energy Policy Project, a massive analysis of energy options which cost \$3 million to complete. But the Congress has so far shown no stomach for taking the unpalatable political decisions needed to slow down energy growth, and federal energy policy is firmly based on the assumption that, although energy growth may be slowed a little, the growth in demand for electrical energy will continue to be large. In the past few years, consumption of electrical energy has been increasing by about 6% a year. Consequently, in order to stave off increased oil imports, new generating capacity will have to be provided by coal and nuclear fission.

Those assumptions are firmly embodied in a long term energy research and development plan published on June 30 by ERDA, which will form the blueprint for ERDA's operations over the next few years.

Reactor safety. In the past few years, the central issue in the nuclear power debate has been whether or not the many safety features built into light water reactors can reliably guard against a major accident which would release large quantities of radioactivity into the environment. The focus of the debate has been an arcane piece of plumbing known as the Emergency Core Cooling System (ECCS), which is designed to flood the reactor core with water if a pipe breaks and the reactor loses its main supply of coolant.

The issue of the reliability of the

ECCS was first brought to public attention by Kendall and Ford of the UCS, who successfully badgered the Atomic Energy Commission into holding prolonged hearings on the matter in 1972 and 1973. Though the hearings failed to resolve the dispute, the AEC tightened its operating standards for ECCS in December 1973, and it is planning a full scale test of the device in an experimental reactor in Idaho in the late 1970s. The critics have not been slow in pointing out that scores of reactors are already being built with an essentially untested safety device.

Some of the steam has, however, been taken out of the safety debate by a massive analysis of the probability of a catastrophic reactor accident, which was carried out for the Atomic Energy Commission by Professor Norman Rasmussen of MIT. A draft of the report, published last year, offered the widely quoted conclusion that the probability of a severe accident resulting in the release of large quantities of radioactivity, is extremely small, that it would result in about 2,300 deaths, and that it would cause about \$6,000 million of damage to property. The report has stimulated a good deal of controversy, however, and some of its findings have been challenged by a separate analysis by the American Physical Society.

In the meantime, however, a fire which occurred in March at the Browns Ferry nuclear power station in Alabama—the world's largest nuclear power plant—reopened the safety dispute. Caused by an electrician checking for air leaks with a candle, the fire knocked out the ECCS system at the plant, and raised a number of questions about the ability of plant operators to react to an emergency.

Plutonium and the LMFBR. Most of the present controversy surrounding the nuclear power programme is concerned with the possibility that plutonium, produced in nuclear reactors, may be recycled and mixed with uranium as reactor fuel. Worries about the toxicity of plutonium have arisen, chiefly in connection with a theory put forward by Cochran and Tamplin of the NRDC, that tiny inhaled particle of plutonium could lodge in the lungs, providing the surrounding tissues with a massive dose of radioactivity. Though the theory has been hotly challenged by various scientists, it is still giving rise to considerable debate. But a more prominent and worrying problem with plutonium is the possibility that quantities of it could be stolen from the nuclear industry and fashioned into crude nuclear bombs, either by terrorist groups or by countries which possess nuclear reactors, but which have not yet produced nuclear weapons. India's development of a nuclear explosive

from plutonium derived from a reactor supplied by Canada has brought the problem to public attention rather dramatically.

Because of uncertainties surrounding the adequacy of safeguards to prevent illicit diversion of plutonium from the nuclear industry, the Nuclear Regulatory Commission (NRC), which has assumed the regulatory functions of the AEC, announced earlier this year that it will probably defer making a decision on whether or not to allow plutonium to be used as a reactor fuel until 1978.

The nuclear industry is upset by the NRC's delay because, it argues, plutonium recycling will be needed to supplement dwindling supplies of uranium; it would reduce requirements for enriched uranium by 10% in the early 1980s. Congress may well have to decide the matter eventually, since a bill outlawing plutonium recycling until the uncertainties have been resolved has been introduced into both the House and the Senate.

Plutonium recycling is itself, however, only a prelude to introduction of the breeder reactor, which is designed to produce more plutonium than it consumes as fuel. The breeder reactor programme is the single most costly energy research and development project supported by the federal government, but its advantage is that, whereas light water reactors would run out of uranium fuel in a few decades, the breeder could provide power from fission for several centuries.

Major disagreements have erupted over the timing of the programme, its cost—the research and development effort alone is expected to swallow up about \$10,700 million, compared with an estimate just three years ago of \$3,300 million—and whether or not other, more acceptable, technologies can be developed in time to make the breeder redundant. A major challenge was offered to the budget for the breeder programme in Congress this year, but it was defeated.

Waste disposal. A major uncertainty afflicting the nuclear programme at present is what will eventually be done with the highly radioactive waste material produced in the reactor core. Although it is generally expected that burying the wastes deep in a salt mine will eventually prove to be safe and acceptable, the concept has yet to be thoroughly tested, and a suitable site has yet to be found. A site was prepared for testing in Kansas in the late 1960s, but it was found to be punctured by abandoned oil and gas wells; the project ran into spirited local political opposition and it had to be scrapped. Consequently, the Atomic Energy Commission announced that it would store radioactive wastes above

FUNDS to support research are becoming scarcer, so it is increasingly important to ensure that the money available is used as profitably as possible. For some years I have been suggesting that we are getting poorer and poorer value for the public money voted for research, and that an increasing fraction is being wasted on unnecessary and complicated administration. One of the fears aroused by the Rothschild recommendations was that they would make for additional complications and further waste. Even the most enthusiastic supporters of these changes cannot deny that there are many more scientists, individuals who were previously themselves engaged in research at the bench, who are now desk-bound planners, and that research funds are also spent on many more non-scientific administrators supporting (or even controlling) the scientific administrators. The hope is that this will result in the remaining bench workers devoting their time more profitably to more important projects.

In the meantime, it may be useful to try to find what sort of organisation is producing the most for the least expenditure. In the past, I have been accused of sentimentality for looking back nostalgically at the small units which operated efficiently in the 1930s, when funds were even tighter than today. I have been told that it is impossible to "put the clock back". The assumption is that the age of string, sealing wax and enthusiasm has gone for ever.

I have therefore been looking with interest at the performance of the Oil Pollution Research Unit of the Field Studies Council. Here we have a small group of young scientists working in converted cellars and outbuildings on a smaller total budget than that enjoyed by many individual academics who have received research council grants for studies which have made little noticeable impact on science or human welfare. At an international conference held at Aviemore in Scotland in April of this year, and sponsored by the Institute of Petroleum and the Field Studies Council, members of the unit described their work. It was clear that this was both important and entirely relevant to the needs of the petroleum industry and to understanding the likely ecological effects of the exploitation of oil reserves. The work fulfilled all the

Lab charges

KENNETH MELLANBY

requirements that the Rothschild proposals are intended to produce.

The Oil Pollution Research Unit (OPRU) has, however, shown that a very high proportion—more than 90% I would estimate—of their funds are actually spent directly on research, paying salaries, equipping laboratories, hiring facilities and visiting sites. The parent body, the Field Studies Council, is itself an admirable organisation, with the least top-heavy administration of any comparable body. They do not have time to interfere in the running of the OPRU, though they are available to give help where this is required. The main lesson to be learned from this research organisation is, once more, that "small is beautiful", or at least that the small unit can still be the least wasteful.

I think that many other organisations could learn from this example. Their overheads are very much higher, though their productivity is, on the whole, lower. We hear many complaints from government departments, who have funds to commission research, that some laboratories run by research councils, or even by other government departments, are in danger of pricing themselves out of the market. This is because most contracts must bear a surcharge of 100% to meet overheads and administrative costs. It is difficult not to suggest that these could be greatly reduced by a simpler administrative structure.

There is even some criticism of university departments, which are

accepting contracts and making a much smaller surcharge. This is, in some circles, considered to be unfair competition. It is suggested that they should be compelled to charge more, for they are accused of not costing their work properly. As one with some experience of university administration, I do not think that this is the case, though the argument might appeal to empire-building registrars wishing to increase their own staff numbers. If I, as head of a department, had accepted a research contract, and it had included all the costs of staff and their equipment and materials, I would not have spent a penny more on running the department, nor would there have been any need for the central university administration to increase its costs. I might have had to write an occasional letter, but I would have hoped to compensate for this, and more, by persuading the research workers to give a few of my lectures on subjects in which they possessed a particular expertise. I would have looked upon my relationship with the contract team as one of symbiosis, and not treated them as parasites.

My main criticism of many university and polytechnic staff today is that they often assume that they cannot do worthwhile research unless they can land a substantial grant for that purpose. Even junior lecturers think they are justified in asking for a graduate research assistant. Yet even when they obtain this extra money, many are obviously less productive than the pre-war lecturer who was lucky if he could obtain a few pounds from departmental funds for extra materials. It may well be that the present shortage of money will have its good results. Research workers may have to eschew problems requiring costly apparatus (much of which is accumulating dust up and down the country) and devote more time to thinking how to tackle problems within their own resources. They may even realise that some of the large grants which have been floating about in recent years have actually been counter-productive. We are said to be facing, in Britain, a financial crisis even more serious than that experienced in the 1930s. We should therefore remember that, in many subjects, it was then that Britain led the world in scientific research. □

the ground in a temporary facility until an ultimate waste disposal method has been found. Earlier this year, however, ERDA announced that it was reconsidering the whole problem and would issue a statement on the matter in due course.

With those disputes unresolved, and

reactor sales at a virtual standstill, the immediate prospects for President Ford's goal of bringing 200 nuclear reactors on line by 1985 looks slim. But, in the absence of a strong, coherent energy policy featuring mandatory energy conservation and massive support for non-nuclear energy

technologies, the nuclear power programme represents the only proven alternative to greatly increased oil imports. Faced with that prospect, Congress will be forced soon to take some controversial decisions. In the meantime, the nuclear energy industry will have to live with uncertainty. □

international news

At the opening last week of the annual conference of the International Atomic Energy Agency in Vienna, the Director General, Mr Sigvard Eklund, expressed confidence in the continuing expansion of nuclear power technology. He suggested that nuclear energy based on fission provided the only immediately available alternative to fossil fuels in spite of recent optimism about the potential of alternative energy sources.

Addressing the delegates of 107 member nations of the IAEA Mr Eklund said that as alternative resources from solar, geothermal and wind power, and from nuclear fusion would not become readily available for some time and that even then those sources would provide less power than current estimates suggested.

Mr Eklund was, however, optimistic that largely under the guidance of the IAEA the problems associated with the use of fission reactors could be overcome. These included three main issues which have recently formed the focus of public debate, namely, the safety and reliability of the reactors, the disposal of radioactive waste, and the need to ensure that the spread of nuclear technology does not lead to a proliferation of nuclear arms development among the non-nuclear powers.

Dealing with the first of these points Mr Eklund said that the IAEA is engaged on a programme to formulate a comprehensive system of international

IAEA head puts faith in nuclear power

by Allan Piper

safety codes and guidelines for nuclear power plants. The agency believes, he said, that the "teething troubles" undergone by the larger reactors have now been eliminated, and that it is no longer fair to regard nuclear power stations as unreliable.

Many of the problems associated with the satisfactory management of waste products remain to be resolved, however. In particular, the IAEA is establishing a standing advisory group to examine the feasibility of burying waste in geologically stable terrain. Referring to that concept Mr Eklund drew attention to the point raised during an earlier agency conference that plutonium formed in the Oklo Formation about 1,700 million years ago decayed quite harmlessly without escaping into the environment.

On the question of preventing an escalation of nuclear weapons proliferation as more countries obtain the materials for developing nuclear power plant Mr Eklund stressed the need for the adoption of internationally accept-

able IAEA safeguards. He expressed disappointment that though the Non-Proliferation Treaty Conference held in Geneva in May expressed strong support for safeguards controlled by IAEA their recommendations had not been considerably more decisive.

Calling upon the present nuclear powers as the major exporters of nuclear materials and technology, Mr Eklund urged them to take the lead by supplying nuclear resources only to those nations prepared to place their "entire nuclear activity" under international safeguards.

He stressed that commercial and political interests should not prevail over that objective, adding that further progress towards a comprehensive ban on nuclear tests by the nuclear powers themselves would assist by setting an example to the developing countries. He also proposed that the explosion of nuclear devices necessary to the development of nuclear technology be placed under international control.

Though Mr Eklund's speech reflects a confidence in the future of nuclear fission as a major source of energy he indicated that IAEA are not discounting altogether other possible sources. The agency, together with the World Health Organisation, is, he said, co-operating with the International Institute of Applied Systems Analysis on a programme to evaluate the viability of every available option. □

M. d'ORNANO, the French Minister for Industry, has presented the conclusions of the consultative commission on energy, chaired by M. B. Gregory, the Director General of the CNRS (National Centre for Scientific Research). This commission was set up to examine the future direction of government energy policy, and includes representatives from a very wide spectrum of interests—specialists, energy users, and "social partners"—so that all shades of opinion can be expressed. Three criteria were drawn up to help the working of the commission—low financial cost, political independence, and ecological and social aspects, but the commission "regretted that it could not report within this framework any coherence in the proposed courses of action". In fact, the commission's report is not always in agreement with decisions reached by the government.

In its plans for 1985, the commission

places special emphasis on efforts to reduce energy consumption. By comparison with 1973 forecasts, the total consumption hoped for would be 240 Mtpc (millions of tons petroleum equivalent) instead of 285 Mtpc, and the amount derived from petroleum products would be 96 Mtpc instead of 178 Mtpc. The report stresses that "this is compatible with an annual growth rate of 5.5% only at the price of a policy involving strict restraint, but it is well worth the effort to attempt to reach this goal". The feasibility of the 5.5% rate as the basis of a working hypothesis has, in any case, been thrown into doubt by some members of the commission. Coal consumption (30 Mtpc) would continue to decline progressively, while gas consumption would rapidly increase to 37 Mtpc.

The recommendations of the commission regarding electricity are very

precise: whereas electricity production would, at the present rate, have approximately doubled by 1985, the commission underlines the dangers of a policy exclusively favouring electricity, it urges that major research and development efforts be made on solar, hydrogen and other energy sources.

The most striking point of the report is without doubt the split which has appeared within the commission over the nuclear programme. Some of its members advocate, for safety reasons, the construction of nuclear power stations of lower output than that proposed by the government, the balance of the energy being provided by traditional power stations even if this seems less favourably economical. M. d'Ornano has perhaps shown excessive optimism in making the report of the Gregory commission public, for it seems to call into question many aspects of government policy. □

France boosts nuclear physics

by Roger Woodham

A NEW experimental facility for 'low energy' nuclear physicists, to be known as the Grand Accélérateur National à Ions Lourds (GANIL), will be included in the French Seventh Plan which covers the years 1976-80. It will cost about £20 million, should be in operation before 1980 and is to be built just outside Caen in Normandy.

As well as being part of the French government's strategy for livening up the French economy by authorising spending on new scientific projects during the next five years, the Caen decision also has implications for the recently acquired French interest in regional policy. With the mood in France at present much in favour of decentralisation, the Délégation Générale à la Recherche Scientifique et Technique (DGRST) has taken the first tentative step towards some sort of regional policy in science by giving the green light to GANIL.

Instead of choosing to build the new accelerator complex in the vicinity of Paris, perhaps at Saclay or Orsay, the DGRST and the Minister of Industry and Research, M. Michel d'Ornano, settled on Caen—a somewhat surprising selection which was not on the list of places like Grenoble, Strasbourg, Lyon and Bordeaux which have been widely canvassed during the past year or so. Cynics like to point out that M d'Ornano is Mayor of Deauville (not far from Caen) and was until last year President of the Regional Council of Lower Normandy. The fact is, however, that Caen is only two hours by a fast train service from Paris and will therefore be easily accessible to nuclear physicists from other countries, a significant consideration given that the French see GANIL as an important international facility.

The GANIL project, which will make available beams of heavy ions ranging from carbon to uranium at energies higher than is or will be possible with machines elsewhere, is the brainchild of a coordinating committee set up by the DGRST in 1972 to look at the whole matter of French support for nuclear and elementary particle physics. (In France these activities come under the auspices of the Commissariat à l'Energie Atomique (CEA) and the Institut National de Physique Nucléaire et de Physique des Particules, the latter being an umbrella organisation colloquially known as IN2P3 and covering all nuclear and particle physics activity in university laboratories and those of the CNRS (Centre National de la Recherche Scientifique).) GANIL was

A comparison of the energy per nucleon available from GANIL (planned) compared with that available (or planned) at other accelerators

dreamt up by a working party drawn from the CEA and IN2P3, and the money required will be provided in equal measure by the two organisations.

There are two somewhat unusual features of GANIL: first, that the main part of the system is to comprise two large cyclotrons, one of which will inject particles into the other, and second that superconducting magnets, which are increasingly in evidence in designs for new accelerators, are not to be used. As to the cyclotrons, the GANIL team maintains that it is only by using this kind of accelerator that high values of the energy per nucleon of a nucleus can be achieved. Certainly, if the promise implied in the figure is upheld, the French will have something to be proud of: over much of the range of atomic numbers the energy per nucleon available from GANIL is several times higher than from other accelerators.

The GANIL team decided against superconducting magnets mainly on the grounds that France does not have enough experience to take what might amount to a very risky step, especially as others have hit snags while building such magnets for accelerators. The team argues, however, that a cyclotron system is absolutely necessary and is

to be preferred to the tandem Van de Graaff arrangements to be used at Daresbury in the UK, for example. Certainly the linear machines at Darmstadt and Berkeley, for example, are capable of accelerating greater numbers of particles per second, and the quality of the beam from a linear machine is on the whole better than from a cyclotron, but when it comes to increasing the energy delivered, the cyclotron seems to win hands down.

Not all users of GANIL will have to avail themselves of the maximum energy available, however. Many of the people who will eventually use the facility are chemists, biologists and so on, and it will often be that they will use beams of particles from the first cyclotron, before they are injected into the second one for further acceleration. In any event, the site for GANIL—which is still a green field on which no more than preliminary geological investigations have been made—is close to the Faculty of Medicine of the University of Caen, and to a college of technology; there is also ample room for interested industrial concerns like electronics companies to set up their own bases nearby so that they can make use of GANIL for their own investigations, on ion implantation, for example. □

ONE of the more practical ideas to come out of the Stockholm Conference on the Human Environment in 1972 was that of setting up some sort of central service for the collection and dissemination of information on a very wide range of environmental matters. Before the conference, some people seem to have envisaged a centralised service actually providing information, or at least providing direct references to precisely where it could be obtained. But a more realistic look at the situation, and in particular an appreciation of the wide range of subjects and problems to be covered, indicated that this would not be feasible, at any rate on a global scale. Even if a centralised system had been a practical proposition, it would be quite impossible to keep information up to date, especially with environmental affairs in their present unstable and rapidly developing state.

In fact, what the conference organisers had had in mind all along was an obvious alternative, in the shape of a referral service. This would not itself provide or store information, but would aim to put its clients in touch with those places where the information they seek could be found, and to do this in an orderly, internationally accepted fashion. After two years of careful planning and consultations with governments, research institutes and other organisations with relevant experience, the International Referral Service (IRS) has recently started to operate. In view of the wide field to be covered, the UN Environmental Program (UNEP) decided to base the service on a number of priorities considered by members of its Governing Council to be of global importance. Because the service must also be useful within individual countries, however, or to clients having purely local interests, it needs to encompass a wider definition of the general concept of "environment" than is generally understood by the UNEP itself in its day-to-day working.

A service that does not itself provide information, but is designed to indicate where that information can be found, will obviously have smaller storage requirements than a centralised direct information service, and will not need such extensive updating facilities; nonetheless, more is needed than the UNEP can provide, although it is not in fact necessary even for the basic information to be centralised. As now set up, therefore, the IRS works through a number of 'focal points', notionally one for each contributing country. A typical focal point has two roles: first, it acts as a centre for the collection of information and, second, it functions as a subsidiary of the IRS within its own country. It will thus be able to

operate in two ways:

- By collecting and storing detailed information not required by the IRS but needed locally.
- As part of the overall IRS network. Operation at the purely local level recognises the fact that most countries now either have, or intend to have in the near future, some sort of environmental control mechanism, which will, however, inevitably trespass on areas already covered by other government departments. The sets of information available within countries are in fact largely in the areas so covered, and

UN environmental service launched

from Peter Collins, Geneva

the national environment organisations are thus best suited to cataloguing sources of such information within their own countries.

Being financed by government and therefore liable to government control, a national focal point also controls itself as regards its clientele. It is expected to evaluate its own sources and to keep out trivial requests, thus giving the system a good deal of flexibility and national control. The only clients other than those approved in this way by the focal points are the members of the UN system, who could be among the biggest users of the new service, and non-governmental organisations having official status. At the other end of the chain, the national focal point can also decide whether or not to accept a request, although it is not anticipated that this sanction will often be applied: a request already passed by the focal point in its country of origin is unlikely to be rejected. The answer to a request goes back through the same channels as those through which it was received.

From the practical point of view, the essential document is the IRS Operations Manual, the international version of which appeared in August this year. This comprises clear and concise guides to the various elements of the service—sources, focal points, and users, giving the purpose and responsibilities of the first two and the procedures to be followed by the last. Because the service must be operable on a multilingual basis, and is essentially designed for computer handling, a complete list of codes is given, any given attribute having the same code number in any language. These codes cover sponsorship, activities, functions, geographical coverage, working language, availability, output and subjects. Two further sections provide computer logic and computer search guides. Initially designed for use with

the programming languages COBOL and PL1, in both of which programs are already available, the system can be adapted to any modern computer, UNEP believes, in less than a week, and plans for conversions to other languages are already in hand.

In practice, a question is coded and passed to the computer, which selects those sources, details of whose stored or accessible information most closely fit the coded question. The answer describes the source (for example, government-sponsored laboratory, research organisation, university department), gives details of its coverage and lists those subjects most (and less) relevant to the query. The client then selects the source or sources that seem most likely to have the information he requires, and contacts them. The UNEP reckon that the cost, as far as the IRS is concerned, is about \$2 an answer. This has, of course, no connection with any fee payable by the user to the selected source.

Some 10 focal points are already operating the IRS, and another 40 or so should begin functioning within the next few months, including a regional one for the CMEA countries and, apparently, the USSR (although Hungary and Yugoslavia will have their own). The manual is available in English, French, Russian and Spanish. Alone of the official UN languages, Chinese cannot be used as it is not suitable for use with a computer. There are already translations into Danish, Dutch, German, Greek, and Italian. The UNEP has held the first of a series of training programmes in the use of the service in Nairobi. One will follow shortly in Geneva, on the use of relevant computer techniques, then two in Dakar (in French) and Mexico City (in Spanish).

The basic idea behind the IRS is to cover the environment in the broadest sense, recognising that people know their own disciplines but need information on others. Countries holding environmental information are not, they point out, necessarily the most advanced technologically; Kenya, for example, has much more experience of running National Parks than have many European countries. The aim at present is to run the service on the basis of the present manual for two years, then to appraise the situation to see what revision is needed. But as it stands, the IRS provides a good example of how a UN agency can function in the way most people think it should: as an international liaison office and clearing house, passing information between member countries or institutions within those countries, and so organised that everyone using the system knows what to expect and can be reasonably sure of getting it. □

As the much delayed jubilee celebrations of the Soviet Academy of Science finally approach, it is perhaps inevitable that the role of the scientist in Soviet society should become a matter for editorial comment in the Soviet press. The relationship between pure research and the immediate needs of the state plans is always a delicate one, and a saving clause referring to the ultimate benefit to the national economy is regularly included in the description of fund-hungry projects of the space programme. The closer connection between the pure scientist and the needs of industry has been one of the fundamental themes of the present five-year plan; this aspect of Soviet science is being stressed in the press preparations for the jubilee. The concept is one fundamental to Soviet thinking—Lenin himself envisaged a total reconstruction of the Soviet economy in which the Academy would play the major role in providing the Soviet Union with “the possibility of equipping itself independently with all the principal forms of raw materials and industry”. Seen in this light, the comment of a *Pravda* editorial (September 20) seems merely an exhortation to renewed efforts: “The duty of a scientist as a citizen is to appear as a champion of scientific and technical progress not only at the writing-desk or blackboard but also to fight for the cause outside the walls of his study or laboratory as well”. The reference recalls, however, the press campaign of September 1973 against Academician Andrei Sakharov, who was accused of betraying his chief duty as a Soviet scientist—that of being a patriot. Sakharov’s “offence” was, of course, his liberal political views, not an excessive preoccupation with pure science. Nevertheless the *Pravda* editorial does suggest that, once again, the slogan of patriotic duty is being used to urge scientists into a greater conformity with Party policy—in this case, the devoting of their talents to the immediate needs of the economy, even at the expense of potentially more valuable basic research—a somewhat ironic way, surely, of celebrating the 250th anniversary of the Academy of Sciences.

● Following recent speculation on the latest Soviet explorations in the Weddell Sea a number of statements made in the Soviet media and through the *Novosti* agency have set out the programme for the latest (twenty-first) Soviet Antarctic expedition, which is due to set out in October. This will include atmospheric sounding, the investigation of deep-level ice cores already taken by advance parties, oceanological investigation in the

Drake Straits, participation in the international South Pole Experiment (Polex South) and a massive survey of the mountainous hinterland of the Weddell Sea. The expedition, led by candidate of Geographical Sciences G. I. Bardin, is to be a large scale one, involving 255 scientists, a flotilla of five ships, including the flagship, the new research vessel Mikhail Somov, an Ilyushin-14 aircraft, four helicopters and five heavy tractors. It will also convey to the Antarctic a considerable amount of new equipment for existing Soviet bases.

Soviet diary

from Vera Rich

● During the past few years, a number of Franco-Soviet joint research projects have taken place, notably in the fields of geophysics and space research. Less publicised has been a biochemical experiment—perhaps because the research was carried out by an all-Soviet team from the Institute of Biochemistry of the Soviet Academy of Sciences, with France providing only some of the specimens. The purpose of the investigation was to establish the chemical constituents of the “bouquet” of champagne. The method used was that of gas-liquid chromatography; the test specimens were of both French and Georgian vintages. It was found that the bouquet is attributable to certain high-boiling-point constituents of fusel oils, notably terpenoid compounds of *cis*- and *trans*-farnesol, and also certain complex esters—ethyl linoleate, ethyl lactate, ethyl caproate, phenylethyl acetate and so on. This contradicts the previous assumption that the bouquet is attributable to highly volatile constituents. Small quantities of highly volatile compounds are, in fact, involved, but these form only a general ‘background’.

● The development of a silk industry independent of China was one of the great aims of the Byzantine emperors, who, when they at last obtained the

secret of silk-worm rearing, promptly made the industry an Imperial monopoly. From emperors to State Planning Committees seem a far cry, yet the Soviet Committee for Science and Technology has recently declared the establishment of native a silk industry to be one of its major inter-industry problems.

The new Soviet silk production is not to be based on the mulberry-feeding Chinese silkworm, but on the caterpillar of the oak egg moth, which is traditionally cultivated in Korea and northern provinces of India. After some 20 years’ research and selection, the Ukrainian Agricultural Academy has succeeded in producing a strain of insect which can be cultivated successfully in the harsher conditions of Poless’e and other areas of Ukraine. By means of hybridisation and selection, an insect has been produced with a life cycle compressed into a single season. Professor N. N. Sinitskii, who was responsible for the project, claims that now silk production need no longer be confined to the Central Asian Republics of the USSR, but can flourish “from the Carpathians to the Urals—wherever there are oakgroves”.

The effect on the ecology of Ukraine and the other western republics of the USSR as not been mentioned. However, in the Irkutsk provinces of western Siberia, another major research project has just been completed; a long term study of the best biological method for combatting a major pest of the Siberian forests—the Siberian silkworm.

● Thirty years ago, largely as a result of the havoc wrought by the Second World War, the European bison was a vanishing species. Now, as a result of careful conservation work in the Byelovezhchaya Forest (which is managed jointly by Poland and the Byelorussian SSR), it has made a remarkable recovery. Partly as a result of this capacity for survival, a team of zoologists in Vologda are attempting to produce a cross between the bison and domestic cattle. Several examples of the new hybrid have already been produced, and they have bison-like features, including increased body-weight, bluish-black hair, a slight hump, and straight sharp horns. The hybrid calves show considerable hardiness, being able to drink ice-cold water immediately after birth and having a considerably more rapid rate of growth during the first 10 days. The hybrid has proved to be fertile, and the first calving from the hybrid cows is due this autumn—after which the fat content of the milk can be established and compared with ordinary cow’s milk. It is hoped that the hybrid will preserve the high yield of the domestic cow.

correspondence

First-year ecology

SIR,—The teaching of ecology at university first-year level probably poses more problems than any other area of biology. Although in general there is agreement as to its desirability, opinions differ considerably as to the methods of implementation. Wide-spread public interest in topics such as conservation and pollution, reflected in pressure from students for courses in ecology, provide powerful reasons for attempting to overcome curriculum problems. We also believe that in an introductory biology course ecology should be presented not only as a subject in its own right but also as having important links with other fields of biology such as physiology, behaviour and genetics. Furthermore, it must be interdisciplinary, involving zoological and botanical aspects, as well as incorporating discussions of the role of micro-organisms in different ecosystems.

To meet these requirements at Bath, we have been reviewing the teaching of ecology at the first-year level in which there is provision for ten one-hour lectures and five two-hour periods of practical work. Our lecture/seminar programme centres around three principal themes—spatial distribution of organisms, the flow of energy in ecosystems and the gene as an element of continuity in populations. On the practical side we have accepted the fact that, at the most, only one field trip will be feasible and we exclude the possibility of vacation courses at this level. The main problem is the practical work which must necessarily be restricted almost entirely to the laboratory and be carried out in the minimum of time. It is also important that, being the first year, various investigations should work. We have therefore directed planning towards the possibility of using simulation experiments with living organisms, many of which have already been tried out in smaller and more advanced classes. The value of these experiments lies in the fact that they aim to reproduce and illustrate in miniature within the laboratory certain selected aspects of the real environment. Study involves not only qualitative description but also quantitative sampling and statistical treatment of results, together with simulation experiments covering such topics as succession, population growth, selection and the estimation of animal

numbers by means of mark, release and recapture experiments.

Simulation, however, has serious drawbacks since it demands extrapolation by the student from imitation to reality. Such an intellectual jump can pose problems. Although in the teaching of ecology, there is no substitute for the experience of a visit to a natural habitat, the introduction into the lecture component of visual aids, such as ciné films, still photographs and slides can help to bridge the gaps.

The inception of a new curriculum should also be associated with a fresh range of objectives some of which will bear on the cognitive field and some on the affective. It is not therefore enough merely to change the nature and quantity of the course content; the methods of teaching and learning must also be adjusted to suit the new requirements. This is particularly true in a complex subject such as ecology which tends to face students initially with a bewildering diversity of problems. Such needs have served to underline the changing role of the lecturer and tutor who acts not only in his traditional capacity of expositor, but also as guide, consultant and stimulator of discussion.

I. C. POTTER

University of Bath

Cheating children

SIR,—I would like to comment on two letters in your issue of September 4 which are related to my work on metal bending. The first is that by Dr Pamplin and Mr Collins, whose interesting study of deception in spoon-bending leads me to ask what is the proportion of children who cheat in other forms of activity in which they are given the opportunity to deceive. I have also seen cases of obvious fraud in my initial tests and have not continued working with the subjects in such cases. I have found so far a ratio of no more than one in six of those who claim metal-bending powers (at least forty subjects) to have been able to achieve the effect in a manner which I cannot explain by deception. This is consistent with the results of Pamplin and Collins.

I would like to suggest that the criteria of bending might have been made more stringent before children were tested in this way, and even while the one-way mirror tests were being performed. Apparently some of the

children still claimed they could spoon-bend without cheating after they had been caught. They might still be able to do so, though only if the conditions are stringent enough will it be possible to get them to turn their attention to using any abnormal powers they possess. The measuring of pressure or at least having a strip of metal taped flat to a desk so it cannot be mechanically bent is necessary here.

In response to Mr Randi, who was very proud of his ability to be able to cheat all and sundry, may I say that his last sentence has remarkable hubris. I would be grateful to learn of Mr Randi's scientific qualifications before I can accept it, and I echo the apt words of the great scientist Sir William Crookes, a past President of the Royal Society, by insisting that when it is necessary to trust my senses I maintain that a physical enquirer is more than a match for a professional conjurer.

May I also recommend to Mr Randi the report of his fellow magicians from Atlanta, A. Zorka and A. Dickson who tested Mr Geller under conditions they felt excluded fraud.

Yours faithfully,

JOHN TAYLOR

King's College, London, UK

Assays

SIR,—With reference to the article of A. Dorozynski (September 11), I would like to make the following comments:

1 The mutagenicity assay, elaborated by Dr Bruce Ames, has been used by the IARC in Lyon for three years within the framework of a continuous collaboration with Dr Ames. Dr Bartsch of the Unit of Chemical Carcinogenesis of the IARC has devised some modifications of the original procedure which have allowed an improvement of the testing efficiency.

2 The IARC is collaborating, and is certainly willing to continue and expand its collaboration, with a number of national laboratories, including the Institut Pasteur in Paris, on the development of screening tests to detect chemical mutagens and/or carcinogens.

3 The IARC is not, and will not be, involved in the commercial dissemination of the "mutatest"

Yours faithfully,

L. TOMATIS

*International Agency for Research on Cancer,
Lyon, France*

news and views

IN the world of professional archaeology of the 1920s and early 30s, the fact that you were a 'Glozelian' or 'Anti-Glozelian' determined who were your friends; this was particularly significant in an academic discipline not unknown for acrimonious controversies. The reason for this in-fighting was based on a reported discovery of artefacts which to most archaeologists were—and to many still are—unacceptable and were therefore labelled as fakes. The first pieces were reported in 1924 by a local farmer, Emile Fradin, who is still very much alive living in the same farmhouse at Glozel, an isolated village south of Vichy in France; these discoveries were quickly followed by many more undertaken by a M. Morlet, a doctor from Vichy. What caused the furore was the fact that these objects were like nothing seen before anywhere in the world and covered an amazing spectrum of different types. There were clay tablets with mysterious incised inscriptions in an unknown language, jars and other ceramics with and without inscriptions, pottery phallic symbols, animals inscribed on bone and pebbles. None of these objects was recognisable archaeologically and even if accepted as something new, many found it impossible to reconcile the different periods represented apparently cheek by jowl; for instance what might conceivably be Neolithic incised stones were apparently found in the same context as clay tablets with inscriptions, which, some said, represented early Iberian scripts.

The controversy raged more or less continuously until the War in 1939. During this time two international commissions of inquiry sat and pronounced exactly opposite decisions and some five law suits were fought with varying results. In Britain the balance against the Glozelians was heavy although on the continent such eminent archaeologists as Professor Reinach were strongly opposed to the notion that deliberate forgery had taken place.

There the matter rested until 1974 when Glyn Daniel, Professor of Archaeology at Cambridge University, decided to dot the i's and cross the t's in his lecture on archaeological fakes and forgeries; he would have a few pottery samples from Glozel tested using the thermoluminescent (TL) technique in order to illustrate their modern date. Exactly the opposite result transpired—the TL measurements clearly indicated

The Glozel affair

from E. T. Hall

that the ceramics were not modern, but seemed to have been manufactured in the Gallo-Roman period (*Antiquity*, December, 1974).

These results, which were later more thoroughly confirmed by further measurements, have again divided the archaeologists. To some the antiquity of the ceramics in particular is no great surprise, although the admixture of these ceramics in the same context as other less acceptable material, such as engraved bone and pebbles of apparently Neolithic date (which are less amenable to dating techniques), makes the unravelling of the whole story very difficult. To other archaeologists the affair is still a distasteful hoax and TL dating must be in error; for them it is similar to telling a physicist that the laws of thermodynamics are no longer valid and, not surprisingly, they find it difficult even to listen.

Where then can the explanation lie? At the symposium on Archaeometry at Oxford University in March, details of the work undertaken by McKerrell at Edinburgh and Mejdahl in Denmark were given, and discussed at length by both physicists and archaeologists. There can now be little doubt that the ceramic material is not modern; preliminary dating results on the bone using the ^{14}C technique tend to support the TL measurements. It has been suggested by some that the ceramics, which were low-fired, could be ancient material such as tiles which had been reshaped and inscribed recently. Though this is a possibility with some tablets, with others it is ruled out because on close examination small bubbles of vitrification can be seen in the grooves of some of the inscriptions. Others have suggested recent deliberate irradiation by X rays or γ rays to give the correct TL dates; such possibilities are ruled out by comparatively simple tests which have indeed been carried out. However it is generally agreed that the archaeology associated with the digging is most unsatisfactory. No properly controlled digging took place except for attempts by both commissions of inquiry of a very limited kind and when 'planting' of finds seemed a distinct

possibility. There is, therefore, no scientific evidence that all of the objects were in fact from the same stratigraphical context or even from Glozel itself.

It is important in these discussions to differentiate between authentication and dating by TL measurements. When a ceramic object has been removed from its immediate surroundings and has been kept in a museum for some years the extent of the radioactive bombardment from the surrounding soil (as opposed to the internal contribution) becomes a matter of conjecture. Dating by TL measurements of such an object must then have much wider limits than when the precise environment is known and an accuracy of $\pm 10\%$ or better can be expected; when the burial environment is unknown the dating accuracy must be subject to greater errors, although in the instance under discussion the approximate level of soil radioactivity would be known provided, of course, that the objects were in fact excavated from the Glozel area. In the case of authentication however we are dealing with a different order of magnitude; in this case we are deciding between an age of 50 and at least 500 years: an error of 1,000% or more. The Glozel measurements would seem to show without doubt that the ceramics are not modern fakes, but it might be a little rash to differentiate with any complete confidence between, say, a Gallo-Roman and a mediaeval provenance. The idea of a mediaeval date becomes a clear possibility after the work of Huxtable and Aitken reported in the latest issue of *Antiquity* (September 1975), albeit on a single specimen. Such a date is perhaps more likely since an archaeologically acceptable mediaeval kiln was discovered on the site. They also point out that McKerrell and Mejdahl's results are based on only five dates and it will be interesting to see, when full publication is made, whether all the objects sampled fall into a coherently dated group, taking into account the wide range inherent in this type of TL measurement.

How does TL dating come out of the controversy? There have during the past four years been some dramatic exposés of modern fakes which had been unsuspected until the advent of TL dating; many Tang wares from Hong Kong, Hacilar from Turkey, Amlash from Tehran and massive Etruscan terracottas from Italy have

all been shown to have been manufactured during the past few years on a large scale and are (or were) decorating shelves in private collections or public museums around the world. These results are now accepted almost unanimously by the relevant authorities and there have been no obvious instances where results undertaken by a reputable laboratory have been shown to be in error as far as authentication is concerned; in other words, so far TL authentication has been shown over many hundreds of samples to be reliable. It would seem unlikely that the Glozel ceramics should be an extraordinary exception to this story of reliability particularly since they do not exhibit any anomalous behaviour during measurement and give entirely normal TL glow curves.

A number of the archaeological objections to the authenticity of the site would be removed if it were found that certain of the objects

were genuine and some false. For instance; one might postulate that the higher fired tablets were genuine, but the weird face urns, phallic symbols, bone and pebble carvings were not; if the ceramics in the latter category had been fabricated from tiles or bricks fired in antiquity and reconstituted, this could give an explanation of their apparent ancient TL date. Measurements being undertaken at Oxford using archaeomagnetic techniques may give some clues as to whether this is a possibility.

It is to be hoped that the projected scientific re-excavation of the site by French archaeologists will proceed apace—a preliminary magnetometer survey has already been undertaken. Although the site has been extensively and randomly dug by many different excavators, if the site is genuine, some objects must remain and their archaeological contexts may help to explain this perplexing problem. □

Polymorphs and amorphs

by Robert W. Cahn

THE central puzzle about glasses is this: why do some melts form glasses on slow cooling while others do not? As with all such broad questions, the golden nugget of understanding recedes further and further as hypotheses pile up. If an explanation is attempted in terms of the viscosity/temperature relation, then one wants to know what determines this reaction; if in terms of critical nucleus size and diffusion rates, then again one asks how these are related to chemical composition. As more and more unconventional glass-formers are discovered, it becomes increasingly difficult to establish what chemical or structural features they have in common. A radically novel hypothesis therefore deserves close attention.

Such an hypothesis is advanced in this issue of *Nature* (page 370) by C. H. L. Goodman. The central observation on which his hypothesis is based is: "A surprisingly large number of the systems which form glasses have as a major (sometimes the only) constituent, a material that exists in two or more polymorphic crystalline forms which differ but little in free energy", and he goes on to exemplify silica, BeF_2 , PbO , As_2O_3 , TiO_2 , Se, S and CdP_2 . He then asks whether polymorphism could be a necessary condition for a material to be a glass-former. The rest of his extremely interesting and well-documented paper is devoted to exploring, admittedly in purely qualitative terms, the implications of his novel hypothesis.

He suggests that, above the glass transition temperature T_g , transient

"flicker-clusters" of all possible polymorphs should coexist, as happens for instance in liquid water. The crucial point here is that none of these clusters can reach a viable size for crystal growth, because the various clusters of polymorph A would be impeded by the clusters of polymorph B, and in particular the separate A clusters could never achieve mutually epitaxial orientation relationships. As the melt cools, eventually the clusters become firmly bonded across parts of their surfaces, leaving liquid-like material in other, unbonded interstices. This stage corresponds to T_g . The role of the minor additives that assist glass formation might well be to concentrate in the residual interstices and reduce the strain resulting from differential thermal contraction of the distinct A and B clusters. (Goodman regards it as an important test of any hypothesis whether it can interpret the important role of some glass-modifier additives which have a major glass-stabilising effect in quite small concentrations.)

Goodman suggests various experimental tests of his ideas: for instance, ways are available to check on the coexistence of microcrystalline clusters and liquid-like interstitial layers. Also, recent work on the radial distribution function in vitreous silica, combined with dilatometric and high-pressure studies, have yielded evidence for the simultaneous presence of several micro-polymorphs. He goes on to point out certain categories of materials which on the basis of his hypothesis should not form glasses: there are thus the begin-

nings of a predictive capacity for the model.

Particularly interesting is the final section of Goodman's paper, where he suggests possible practical implications of his ideas. Thus, the solid cluster/liquid layer model implies that near T_g a glass might behave as an effective absorber of gases, like a zeolite, and points out that this is consistent with the known action of glass films on the surface of semiconducting devices. He suggests that carbon melts containing 'solvent catalysts' such as iron or nickel (used for diamond synthesis) might be capable of being quenched into the glassy state. Finally, he suggests that Griffith cracks, which determine the tensile strengths of glasses, might be controlled by the microstress systems and chemical heterogeneity of his postulated heterocluster arrays. He does not say it, but it might well be that the scale of the cracks (and hence strength level) would be determined by the size distribution of the clusters, and one then becomes interested in what determines this distribution!

One feature of many oxide glasses to which Goodman does not address himself is the observation that many (perhaps most) such glasses undergo liquid-liquid separation above T_g : electron microscopy and X-ray small-angle scattering both show that disperse drops of liquid separate out in a matrix of liquid of distinct chemical composition. It is not immediately clear whether Goodman's hypothesis would imply that each liquid phase needs to break down into arrays of two (or more) types of polymorphic microclusters, or whether it suffices if one phase does so. In any case, it would appear that in view of the prevalence of liquid separation, Goodman's ideas imply that there are often two distinct levels of structural heterogeneity in a stable glass.

This paper will suggest to the reader all sorts of new consequential hypotheses and various kinds of experiments to follow them up. Whether or not time fully confirms his ideas, his paper will undoubtedly prove to be of seminal importance. □

Bølling interstadial in Britain?

from Peter D. Moore

THE elucidation of climatic fluctuations at the close of the last (Devensian) glaciation in Britain is fraught with difficulties (see *Nature*, 251, 185; 1974). One of the major controversies centres upon the events leading up to the so-called Allerød interstadial; in continental Europe a warm period (termed the Bølling interstadial) is believed to have preceded the Allerød,

and there is some indication of another warm period before the Bølling, called the Susaca interstadial (van der Hammen and Vogel, *Geol. Mijn.*, **45**, 33; 1966). In Britain, evidence even for the Bølling is scant and it is widely believed that its influence upon contemporary vegetation was of such a nature that it cannot be distinguished from the succeeding Allerød. Not all palaeoecologists are of that opinion however.

Last year Burrows published the results of his analysis of plant macrofossils from a late Devensian lake site at Nant Ffrancon in North Wales (*New Phytol.*, **73**, 1003; 1974). This site had previously been worked upon by Seddon (*Phil. Trans R. Soc.*, **B244**, 459; 1962), who described a typical sequence of sediments and fossils suggestive of a cold/warm/cold development in late Devensian climate. The new core studied by Burrows, however, revealed a rather different sequence. The organic sediments, often indicative of the Allerød interstadial in British sites, was found, and above and below it were clays with a stony content and with macrofossils indicative of colder conditions. But within the lower clays, about 26 cm below the supposed Allerød, were silty muds, rich in organic matter, and containing plant fragments indicative of relatively warm climatic conditions, including tree birch and *Filipendula ulmaria*. Naturally, this stratigraphic profile, with two organic layers, leads one to speculate that the Bølling interstadial has at last been found in Britain.

It seems very strange, however, that the Bølling should make its effects felt in the mountainous regions of Snowdonia, and yet should not be evident in the many lowland sites which have been studied. In support of his contention, Burrows quotes the data of Crabtree at Cors Geallt, just 10 km from Nant Ffrancon. There, a similar but very thin, organic band was reported in the pre-Allerød clays (*VIII^e Congrès INQUA, Paris*, **1**, 217; 1971), but the arrangement of pollen sampling within the core in question does not permit its clear interpretation as the product of a Bølling interstadial.

The interpretation of cores, either in temporal or climatic terms, on the basis of their stratigraphic sequence alone is a risky business. One needs absolute dates, in this case radiocarbon dates, before such a sequence can be understood. Burrows has recently published some dates from his Nant Ffrancon core (*New Phytol.*, **75**, 167; 1975), but unfortunately the difficulties are still not resolved. Of the four dates he has obtained, he is forced to dismiss the lowermost two as gross underestimates, possibly resulting from contamination. The lowest acceptable

date comes from the basal layers of the upper (supposed Allerød) organic layer, and is $11,900 \pm 500$ b.p. The commencement of the Allerød is conventionally dated at 11,950 b.p. (Godwin and Willis, *Proc. R. Soc.*, **B150**, 199; 1959), so Burrows' date confirms these deposits as belonging to the Allerød interstadial, as it is normally understood in the British context. Although this date still allows the Bølling interpretation which Burrows sets upon the lower organic layers, it does nothing to confirm this. When one takes into account the possibility of rapid sedimentation of the intervening clays and the large standard error of the date quoted, it is still possible that the lower muds also belong to the traditional Allerød.

The case for an undisputed British Bølling therefore still remains open. A more important fact emerges from this involved controversy, however. Despite a plethora of regional information on late Devensian sequences within the British Isles, we still have no type section at which our distinctively British sequence can be defined. No amount of pro-European feeling can excuse the casual and largely inaccurate use which we make of such terms as 'Allerød' and 'Bølling', which have only been defined adequately in their continental context. An intensively studied British type site might at least remove some of the suspended sediment from these currently disturbed and cloudy waters. □

Photoperiodic regulation of insect growth

from our Insect Physiology Correspondent

THE arrest of the process of growth in insects that is known as diapause may occur at different phases of embryonic development, during larval growth, in the pupal stage or in adult reproduction. Diapause used to be defined as an 'inborn' arrest because it appeared to be uninfluenced by environmental changes. But that was because the 'sensitive period', during which induction of the arrest takes place, often occurs long before the actual arrest appears, and the inducing factor was therefore overlooked. In recent years increasing attention has been given to the nature and regulation of the sensitive period itself. A recent paper by D. S. Saunders (*J. Ent. (A)* **50**, 107; 1975) deals with these phenomena in the flesh-fly *Sarcophaga argyrostoma*; it is an instructive short paper because it reviews and confirms earlier observations on this insect (and other insects), contributes some important new discoveries, and generally illustrates the modern approach to the subject of diapause.

The flesh-fly *Sarcophaga* has a diapause controlled, as usual, by photoperiod. Sensitivity to photoperiod begins while the embryos are within the maternal uterus (in these flies the eggs hatch within the common oviduct) and continues throughout larval development, to end at the time of puparium formation. A short daylength of less than 14.5 h in 24 h gives a high proportion of diapausing pupae; larvae raised at a long daylength exceeding 14.5 h give rise to pupae with uninterrupted development. As in other insects a definite number of short- or long-day cycles is required to induce the necessary switch. As the author had earlier shown, these two variables (1) the length of the sensitive period, that is, the length of larval life and (2) the number of short-day cycles required to raise the proportion of diapause pupae in one day's batch to 50%, have different temperature coefficients.

The length of larval life is highly dependent on temperature ($Q_{10}=2.7$), whereas the 'required day number', as defined above, is largely compensated for temperature change ($Q_{10}=1.4$ or less). Consequently, at high temperature (26 °C) the larvae reach puparium formation and their sensitive period comes to an end before the required number of short-day cycles has been experienced, and development proceeds without interruption. Whereas, at a low temperature (16–18 °C) the sen-

A hundred years ago

THE *Photographic News*, in speaking of "Photography and the Illustrated Press," gives some examples of the extent to which the latter is now dependent on the photographic art. The *New York Daily Graphic*, besides often executing its pictures from photographs, employs a photo-mechanical process in the production of some of its work. At the office of the *Moniteur Universel*, which is one of the most extensive printing and publishing establishments in France, arrangements are being made for large photo-printing works, as well as for producing coloured pictures by M. Leon Vidal's photo-chromic process. In this country photography is used to aid the artist in sketching to a great extent. One of these days, no doubt, the *News* believes, we shall have our papers illustrated by photographs *pur et simple*, but even now photography has far more to do with the execution of the illustrations in our journals than most people may be aware of.

from *Nature*, **12**, 503, October 7, 1875.

sitive period of development is prolonged, sufficient short-day cycles can occur and the incidence of pupal diapause is high. Moreover, the length of larval life is shorter at long daylengths than at short daylengths and this will reinforce the effects of temperature.

The author now tests this interpretation by exposing larvae to short-day cycles (LD 12:12) and borderline temperatures of 18 and 20 °C, and then varying by other means the duration of larval development and so the sensitive period. The most effective means of accelerating puparium formation, and so curtailing the sensitive period, was by overcrowding larvae in a limited quantity of meat; and as predicted this reduced the incidence of pupal diapause. (Premature extraction of third instar larvae from the culture, or exposure to pure CO₂ for 24 h had comparable effects.) The sensitive period was lengthened by allowing larvae to wander in wet sawdust, which defers puparium formation; this treatment increases the incidence of pupal diapause.

The theory that insect diapause results from an arrest in secretion of the hormones necessary for growth (or reproduction) was put forward more than 40 years ago and is now fairly generally accepted. Precisely how photoperiod controls hormonal activity is not known. In general it is thought that long or uninterrupted nights are inductive in the diapause-promoting sense, whereas short or interrupted nights are inductive in the development-promoting sense. There is evidence that both effects are accumulated by the photoperiodic counter, the former to a threshold at which, for example, brain hormone secretion is suppressed, the latter to a point at which secretion is released, thereby leading to ecdysone secretion by the ring gland, puparium formation, growth, and eclosion. What is it that is being summed? The author argues convincingly that the summation of successive photoperiods cannot be the summation of cryptic effects of ecdysone. It seems more likely that the mechanism for summing photoperiodic cycles lies in the brain itself where the release of the brain hormone is regulated. □

How birds reach home

The 14th International Ethological Conference was held at Parma, on August 27–September 5

from John R. Krebs

THE problem of how migrating birds and homing pigeons navigate still

remains unsolved in spite of intensive research efforts in the past few years. Over twenty years ago, Gustav Kramer suggested that in order to fly from an unfamiliar place to a geographically distant home site, a bird would need information analogous to a map (on which to read its own position and that of home), and a compass (to choose the appropriate direction indicated by the map). It is now well established that both migrating song birds and homing pigeons (on which much of the experimental work is done) have up to three types of compass—based on the Sun's azimuth, star patterns and the resultant of the Earth's magnetic field, but the nature of the map remains elusive.

F. Papi and his colleagues from Pisa presented a synthesis of their experimental evidence supporting the idea that pigeons use an olfactory map of windborne smells to home from an unfamiliar release site. The results are impressive. In one experiment three groups of pigeons were reared in outdoor aviaries side by side. Two of the groups were exposed to abnormal wind directions by an arrangement of screens that deflected the wind through 90° clockwise or counterclockwise, and the third group acted as a control. When the pigeons were released 105 km from home, the control group headed straight home, the group exposed to clockwise wind rotation headed off 65° counterclockwise from home, while the counterclockwise group deviated clockwise by a similar amount. In a second series of experiments, pigeons were raised in outdoor aviaries and exposed to artificial winds from the North or South bearing the scent of olive oil or α -pinene. The birds were later released 26 km West of home, and flew South if a drop of 'North-wind' scent was placed on their nostrils before release, while they flew North if treated with the 'South-wind' scent. These and other experiments all suggest that the birds learn to associate particular scents with winds coming from particular directions towards the home loft, and that they use this information together with the concentration of scent at the release site, to construct an olfactory map showing the position of the release site in relation to home.

Although the Pisa group's results look convincing, W. T. Keeton (Cornell University) reported that he was unable to replicate them, and the reason for this discrepancy is unclear, although as one Italian delegate suggested, the Italian countryside, redolent with the aroma of olives and garlic, may be more conducive to olfactory navigation than are the extensive deciduous forests of upstate New York. In any case, it seems much less likely that an olfactory map would be used by long distance migrants travelling thousands of miles from

northern temperate regions to the tropics. Many of these birds travel at night, and for some years it has been known that they use the pattern of the stars as a compass. W. Wiltschko (Frankfurt University) reported some very neat experiments showing that the star compass is 'set' according to the magnetic compass that these migrants also possess. Wiltschko recorded the spontaneous migratory fluttering movements of garden warblers and robins in small circular cages. When the birds were allowed to see the sky on a clear night in a normal magnetic field, they fluttered in the usual migratory direction, roughly South in the autumn and North in the spring. When magnetic North was artificially rotated by 120°, the birds correspondingly altered their heading, even though the stars were still visible. Robins took longer to adjust than garden warblers, so they seem to take more notice of the stars. Wiltschko then showed that the robins could be trained to use a totally artificial pattern of 'stars' as a compass, if they were first shown the pattern in association with the Earth's magnetic field. The magnetic field is used to 'calibrate' the star pattern, which can then be used on its own. One may well wonder why the birds use a star compass at all if it has to be set with reference to a magnetic compass; perhaps it requires longer to 'read' the magnetic compass, so that the visual compass is used for quick reference while the bird is in flight. Finally, the big remaining mystery surrounding the magnetic compass, is how the bird's sensory system detects the Earth's magnetic field. □

Conservation of marmosets

from J. P. Hearn

An international conference on the Biology and Conservation of Marmosets convened by the National Zoological Park, Smithsonian Institution was held at Front Royal, Virginia on August 18–21.

MARMOSSET monkeys are becoming more common in laboratories and rarer in the wild. The potential of marmosets as models in human oriented studies in immunology, virology, reproduction, contraception, teratology and other fields, is just starting to be recognised, but already some species are impossible to obtain and several South American countries have banned the export of marmosets completely.

Recently, sixty scientists from the United States, South America and Europe participated in an International Conference on the Biology and Conservation of Marmosets and the picture that emerged gave cause for concern.

Several species of marmosets—the lion tamarins, the buff headed marmoset, the white eared marmoset and the cotton topped tamarin (*Leontopithecus* species, *Callithrix flaviceps* *Callithrix aurita* and *Saguinus oedipus oedipus*)—are threatened so severely that they are near extinction. The major threat to these animals is the clearance of their natural forest homelands. The lion tamarins from Brazil are now dependent on only 2% of their original natural range and not more than 600 are thought to survive in the wild.

Three suggestions were made to rectify the situation: A total ban on the export, shooting, or interference with the endangered species; urgent studies in the wild by census and observation; and careful management of the remaining home environment. These animals depend on particular types of trees for food and nesting holes. Planting of such trees, with shelter holes artificially bored in them if necessary, and a supply of additional foods, would assist the survival of these animals in the present unnaturally reduced environments to which they are restricted. As any delay in the application of effective measures may well prove disastrous, the conference asked for assistance from conservation organisations and the governments of the source countries.

Marmosets used in research are usually the common marmoset, the saddle-backed tamarin and the moustache tamarin (*Callithrix jacchus*, *Saguinus fuscicollis* and *Saguinus mystax*). These are not immediately threatened but may become so as growing research needs outstrip the replacement of natural wild stocks. The threats to their continued supply from the wild are the appalling losses suffered at present during shipment from the wild to the user countries and the accelerating rate of deforestation in developing South American countries.

In this case there are several longer term solutions that can be applied. Marmosets, and in particular the common marmoset, are prolific breeders in and out of captivity. They can be maintained in self-replacing colonies that are inexpensive to run compared with colonies of the more conventional, larger laboratory primates. Therefore, breeding centres should be established on a large scale commercial basis both in the countries of origin and the countries where marmosets are used in research. Laboratories should also develop colonies that are self-replacing in order to become independent of supplies from the wild.

In the shorter term it is essential that the conditions in which marmosets are held between capture in the wild and arrival in the laboratory be greatly improved. Of necessity this control must be applied in the source countries, by the rigorous application of export quotas and by inspection at the export centres. At present only about 10% of marmosets caught in the wild survive the various stages necessary before they become established in the laboratory. This has resulted in an unreal escalation in demand. The situation could easily be improved as marmosets are amenable and adapt very easily to captivity if given the right conditions.

At a time when the need for primates in research is growing and supplies from the wild are dwindling, many scientists are looking to the smaller new world monkeys as an alternative to the more conventional macaques. The marmosets are receiving particular attention as they are small, inexpensive, easy to manage and breed well in captivity, but if their exploitation is not more carefully managed than it has been in the last five years there will be disastrous consequences for the wild populations. □

New light on luminescence

from G. F. J. Garlick

An International Conference on Luminescence was held in Tokyo on September 1–5. The full proceedings will be published in an issue of the *Journal of Luminescence* in 1976.

New lamps for old might have been the cry at many previous luminescence conferences, particularly because of the developments in fluorescent lighting, electroluminescence and cathode ray tube phosphors. This year in Tokyo, however, it was a different transition. Having seen its offspring, the laser, safely launched, luminescence research is utilising the high intensity and short pulse lifetime features of lasers to enter a new phase. It is now possible to look at the very early stages of excitation and at the fascinating effects of high excitation densities. It is no longer legitimate to separate the emission processes from absorption and excitation and one can hardly sustain the definition of luminescence which distinguishes it from the Raman effect. The invasion of the pre-relaxed states of both inorganic and organic systems by experiment and theory was well described in the various review papers at the conference. The process of luminescence is now

analogous to the 'compound nucleus model': the luminescing system interacts coherently with the exciting radiation field and relaxes by various channels. K. K. Rebane (Institute of Physics, Academy of Sciences of Estonia, USSR) showed that it is possible to look at the unrelaxed states at ordinary excitation levels in the steady state but there seems to be no doubt that picosecond techniques and high intensities are needed to sift out the detailed stages from coherence interaction to the dephased, relaxed state. As exemplified by the large number of original contributions, high intensity studies reveal, through their characteristic luminescence spectra, new entities such as the interacting exciton-photon—the polariton; the excitonic molecule or bi-exciton and, given the right physical conditions, the condensed exciton system—the Bose droplet. The latter has been detected in sizes up to 1 mm as reported by C. D. Jeffries (University of California, Berkeley). Although such phases are not yet very evident in the organic systems, the spate of papers on exciton migration and interaction in aromatic crystals leaves no doubt that larger co-operative entities are likely to be found there also. The larger-than-usual collection of papers on organic crystals had a unifying influence on the meeting which should be strengthened in the future. There was also an important group of papers from P. M. Rentzepis (Bell Laboratories, New Jersey), R. Kopelman (University of Michigan) and V. J. Koester *et al* (Purdue University) which showed that picosecond and other spectroscopic-time resolution techniques can be applied to luminescence and related optical processes in chlorophylls with a good chance of unravelling the initial excitation and transfer mechanisms in photosynthesis.

The radiationless transitions which detract from luminescence efficiency are usually only indirectly observed through quenching of luminescence. M. B. Robin (Bell Laboratories, New Jersey) has, however, detected the heat pulse from a non-radiative transition by means of the 'second sound' pulse propagated in superfluid helium and recorded by a superconducting lead bolometer. In a different experiment at helium temperatures, N. Riehl (Technical University, München), has shown that it is possible to detect single phonon propagations in crystals by their activation of electrons from very shallow traps.

Among new luminescent materials reported were some stoichiometric rare earth compounds (such as NdP₂O₇) developed by M. G. Danielmeyer (Max-Planck-Institut für Festkörperforschung, Stuttgart) needing no impurity doping and having high efficiencies as

laser crystals. M. Genet *et al.* (Institut de Physique Nucléaire, Orsay) described a ThBr₃ phosphor, efficient as a scintillator and capable of excitation by a β source to give enough light to a photovoltaic cell to provide an energy converter of about 0.3% efficiency! To these we may add recent phosphors, reviewed by A. L. N. Stevels (Philips Research Laboratories, Eindhoven) which may be used to give three component fluorescent lamps, substitutions for the sulphide phosphors of cathode ray tubes and for the current X-ray intensifying screens. All of these materials utilise the features of rare earth activators in a variety of host crystals.

Among new effects reported at the meeting, E. Nakazawa (NHK Broadcasting Science Research Laboratories, Tokyo) described photon absorption and emission at twice the energy of the individual level separations of cooperating pairs of rare earth ions in an yttrium phosphate crystal. One might ask, what has happened to the former extensive interest in electroluminescence? There were some papers on the subject at the meeting but lack of financial largesse has forced research into a narrower range of materials, notably into studies of the deep lying band gap states in GaP, GaAs and their alloys and into other features which might be holding down the efficiency of light-emitting diodes. This basic work seems preferable to free ranging over every possible electroluminescent system although there is still an unsatisfied hope of a breakthrough in high band gap crystals like ZnS and ZnSe.

The institution of informal discussion groups on specific topics, such as picosecond techniques, proved very popular. Organisation in all respects was excellent and set a high standard for emulation at the next conference to be held in Paris in 1978. □

Neutron diffraction in Holland

from G. E. Bacon

A meeting on New Methods and Techniques in Neutron Diffraction was held on August 5-6 at the Reactor Centrum Nederland near Amsterdam. Papers presented at the meeting will be published as a report of the Reactor Centrum Nederland.

AFTER attending international meetings on neutron diffraction for a quarter of a century it was a new experience to go to one at which only 8, out of an

audience of 127, came from the United States. At first sight such a circumstance at the Reactor Centrum Nederland at Petten, near Amsterdam, may be thought simply to underline the increasing financial difficulties which face those who have to travel large distances to keep in touch with their scientific colleagues. More fundamentally the unusual ratio reflected the dividend which is now being paid for the Franco-German, and latterly and more tardily the British, collaboration in the High Flux Beam Reactor at the Institut Laue-Langevin in Grenoble. More specifically, much of the discussion at this meeting reflected the success of the German investment in guide tubes and other neutron optical devices inspired by H. Maier-Leibnitz. The papers were restricted to topics relating to elastic scattering only.

The six sessions made it clear that the number of available techniques in this field is immensely larger than it was 5 or 10 years ago, mainly because a high flux makes a practical possibility of many methods which developments in computing had made possible, in principle, some years earlier. The employment of position-sensitive detectors, contrast-variation in small-angle scattering by biological substances, polarisation analysis and powder-profile refinement are now producing scientific results concerning interesting materials, rather than demonstration experiments. For example, in protein molecules, by labelling different parts of the molecule with selective deuteration, it is possible to do much more than determine an average radius of gyration. By small-angle scattering also (G. Lippmann, Institut für Festkörperforschung der Kernforschungsanlage, Jülich, BDR) the dimensions of the nickel-depleted zones in invar alloys have been found. By profile-refinement, structures have been determined (J. C. Taylor, Chemical Physics Division, Lucas Heights, Australia) for a wide range of uranium compounds which are very intractable for growing and maintaining as single crystals. D. Hohlwein (Institut Laue-Langevin, Grenoble) indicated the practical possibilities of photographic detection, showing, for example, neutron Weissenberg photographs of the superstructure reflections from the mineral labradorite. M. Schlenker (Laboratoire du Magnétisme, CNR, Grenoble) showed how the penetrating ability of neutrons enabled topographic studies to be extended to the interior of crystals, thus effectively studying a section through a crystal without the disadvantage of having to destroy it by cutting a slice.

Rather belatedly perhaps, work has thrived on the use of pulsed sources, including particle-accelerating machines, for neutron diffraction experi-

ments using time-of-flight techniques. This is not solely because of the advantages which the fixed geometry yields for the production of cryostats, furnaces and high-pressure cells but probably with an eye to the future, where the next generation of neutron sources may well not be the conventional reactor, but some kind of neutron booster or spallation machine capable of increasing neutron beam intensities by another order of magnitude. □

From babble to Babel

by Miranda Robertson

The Third International Child Language Symposium was held in London on September 3-5.

It was linguistic theory, and in particular the transformational grammar of Noam Chomsky, that led to the recent surge of interest in child language; but while the interest is unabated, it seems that the influence of linguistics has begun to wane. Chomsky's view that the deep structures of his transformational grammar reflect the innate organisation of the neural substrates for language led researchers to look for evidence in the earliest utterances of infants and in fundamental similarities in the first sentences of children speaking widely different tongues. It is now generally felt however that transformational grammar has failed to illuminate either.

Richard Cromer (MRC Child Development Unit, London), as chairman of the session on the acquisition of syntax, attempted to categorise the advances and retreats. For example, as he pointed out, there is less work on syntax but more on semantics. That is partly because of a belated realisation that it is impossible to separate the two, since in order to look at how a child starts to use syntax to express his meaning it is necessary to know what meaning he intended to express. And it is the need to understand the child's semantic intentions that has led to another important reorientation (or in Cromer's terms, an advance)—from the dogmatic to the pragmatic approach. That has led to the use of the ethological research strategy promulgated perhaps most notably by Professor Jerome Bruner (Oxford University).

What, then, have psycholinguists learned by watching the emergence of infant speech in its natural habitat? Elizabeth Bates and her colleagues (University of Rome) have been able to follow the progression from gesture to first word in a longitudinal study on Italian children from the age of 2

months. It is commonly accepted that the single-word utterances of infants can be divided into imperative and declarative modes, at a stage at which differences in intonation and gesticulation have to substitute for syntax to indicate whether the intention is to demand something or merely to point it out. Bates has been able to trace the development from imperative and declarative gesture alone to the later association with words.

As any mother knows, and as Linda Ferrier (University of Bristol)—who is one—pointed out, the meanings of babies' first words are frequently complex and usually idiosyncratic, because the child has to encode in one word the semantic content of a sentence and he generally does so by presuming on his shared experience with his mother. For example, Ferrier's own child used the word "cat" to request a drawing, because cats were what Ferrier habitually drew.

Because the single words of small children are so loaded with significance, they have come to be known in the jargon of the field as holophrases, whose interpretation is central to an understanding of how children develop more complex linguistic skills. Dr Patricia Greenfield (University of California, Los Angeles) therefore aroused particular interest with a report of preliminary observations on two children (one hers) on how a child selects one of several appropriate single words to utter in a given situation. Her thesis is that the decisive factor is the word's information content, somewhat intuitively defined in terms of novelty or unexpectedness. The child will thus draw attention to the aspect of a situation which surprises him and may be new to you; which seems a sound functional basis for communication but has no obvious linguistic implications.

Linguistic factors in the acquisition of speech proved generally elusive. Elizabeth Sharpless (City University of New York) found linguistic complexity accounted less well for the order of acquisition of the personal pronouns than did the part played by the child in her experiment. The crucial factor was whether he was a participant in the dialogue, or an onlooker.

H. H. Chipman (Geneva University), following the development of comprehension of possessive pronouns, remarked that at the earlier stages the child's interpretation of a sentence is quite independent of pronoun reference and seems to be based entirely on his presuppositions about the world. That sort of work exposes the need to consider a child's linguistic development in the light of his cognitive development in general, and David Ingram (University of British Columbia) and Bates and

her colleagues have been attempting a systematic study of the relationship between linguistic development and Piagetian cognitive stages. That has involved both of them in some redefinition of one or two of the stages but does not threaten Piaget's view that language develops as part of the child's general capacity for symbolic expression.

Comparisons on the speech of children of different nations, too, yield cognitive rather than linguistic universals, according to D. I. Slobin (University of California, Berkeley), who spoke on his own work and that of F. Antinucci (CNR, Rome) on children speaking Italian, Serbo-Croatian and Turkish. In general, the syntactic errors common to all children can be traced to cognitive problems inherent in what they have to express. Purely linguistic difficulties vary between languages so that, for example, Yugoslavian children are slower to grasp inflection, which is complex in Serbo-Croatian, but quicker than Turkish children to grasp relative clause structure, which is particularly difficult in Turkish. All this raises implicitly the question Cromer made explicit at the conclusion of his assessment of the field: should language learning be considered separately from other kinds of learning? He did not venture an answer, but on the basis of evidence presented at the symposium it should be no.

A. Buffery (University of London) presented a review of recent anatomical and psychophysical evidence for genetically determined asymmetry in the structure and function of the human brain which was widely regarded as evidence for the innateness and the uniqueness of linguistic abilities. But the anatomical evidence rests on an enlargement of part of the left temporal lobe in about 60% of neonates; and there is psychophysical evidence for functional asymmetry in visuo-spatial as well as linguistic skills. It may be legitimate to conclude that man is innately endowed with some elaboration of the cerebral cortex that enables him to use language, but not that it is qualitatively different from whatever allows him to do arithmetic, for instance.

It is beginning to seem that it may be a mistake to investigate the acquisition of language *per se*; and it should perhaps not be very surprising that philosophical linguistics have in the end relatively little to contribute. For one thing, language as spoken to and by children is very different from the sophisticated instrument it becomes in the hands of philosophical linguists. Roger Brown's frequently quoted point, that it was unlikely that a child could ever learn to talk from listening to the speakers at a learned conference, was

well taken, and several speakers addressed themselves to the question of how adults (and especially mothers) adjust their speech to talk to children.

Perhaps one of the most striking differences between children's speech and that of adult academics is that while the child's speech is generally strictly functional, the academic's is often counter-functional. Children thus use their limited lexical and syntactic resources to make their meaning clear, whereas academics may devote all the riches of theirs to obscuring it. Examples were not absent from the papers delivered at the symposium. □

Cosmic rays at Munich

from a Correspondent

The 14th International Cosmic Ray Conference was held at Munich on August 15-29.

A CLAIM for the detection of a new particle or interaction process seems to have become a regular feature at successive biennial cosmic ray conferences. This year it was the turn of the Monopole. In a specially arranged lecture, P. B. Price (University of California, Berkeley) presented the facts to a sceptical audience of some 500 cosmic ray physicists. The evidence is the track of a particle passing through a balloon-borne stack of Cerenkov film, nuclear emulsion and lexan sheets. The researchers (P. B. Price, E. K. Shirk, W. Z. Osborne and L. S. Pirskey) argue that in a stack of 33 lexan sheets the particle produced a track expected of either a nucleus with $125 \leq Z \leq 137$ and velocity $\geq 0.92c$ or a magnetic monopole with a magnetic charge $= 137e$. The Cerenkov/emulsion data indicated that the particle was moving downwards with $v/c = 0.5 \pm 0.1$, and was either a nucleus with $Z \sim 80$ or a monopole of charge $137e$. The only common explanation is hence the monopole. The evidence looked good to a critical audience.

Subsequent discussions, both in and out of session, produced one major attack on Price's conclusion. This came from P. H. Fowler (University of Bristol) who argued an alternative explanation in terms of a nucleus of charge ~ 82 interacting twice in the lexan stack and losing three units of charge at each interaction. By the end of the fortnight it was difficult to find many people who were highly convinced by Price's arguments. The most popular attitude was to wait and see.

The cosmic ray field today covers a vast range of topics 'from quasars to

quarks' and this was reflected in the more than 800 original papers presented at the conference.

On the more traditional cosmic ray stage Price and Shirk also presented data on the distribution of heavy nuclei ($Z > 65$) in cosmic rays obtained from a 1.3 m² lexan detector aboard Skylab. These researchers have obtained data with very high charge resolution and conclude that the measured charge distribution in the vicinity of the Earth at ~ 0.5 GeV per nucleon strongly favours synthesis of these cosmic rays by the r-process (rapid neutron capture) within the last 10^7 yr.

Measurements of cosmic ray particles at very high energies ($> 10^{17}$ eV per nucleus) are made indirectly by means of the extensive air showers (EAS) produced in the atmosphere. Conclusions on the composition of the particles at these energies are still far from definite. The energy spectrum of the primary particles is however, now becoming well established up to 10^{20} eV per nucleus. Further analysis presented by the University of Leeds group, using data obtained at the Haverah Park EAS detector array, gives added weight to the evidence against there being a cut-off in the energy spectrum $\sim 5 \times 10^{19}$ eV. Such a cut-off has been predicted to arise from the interaction of the microwave background radiation (2.7 K) and the cosmic ray particles. The absence of a cut-off seems to be inconsistent with the universal abundance of both the microwave photons and the high energy cosmic ray particles.

Moreover, strong evidence seems to be accumulating for a distinct anisotropy in the celestial arrival direction of the highest energy cosmic rays ($\sim 10^{19}$ eV). As A. A. Watson (University of Leeds) emphasised, the two highest energy events recorded at Haverah Park ($> 10^{20}$ eV) both come from directions close to the North Galactic Pole—strongly indicating a non-Galactic origin. Arrival direction analysis of 'muon-rich' EAS (Nottingham University group) gives indication that heavy cosmic ray primaries at lower energies (10^{17} – 10^{18} eV) may also show anisotropy in a similar direction.

From both interest and necessity cosmic ray physicists have to concern themselves with high energy nuclear physics as well as astrophysics. Previous claims for the detection of tachyons and mandelas (heavy, long interaction length particles) in cosmic rays have unfortunately had to be withdrawn at this conference. Moreover none of the recent searches for fractionally charged quarks amongst the secondaries of cosmic rays have proved positive. Other new phenomena still do seem to be present at these energies, however, most notably the X particles discovered

by the Japanese emulsion group. Also it seems to be increasingly difficult to reconcile EAS data with the sealing model of nuclear interactions. \square

The breakdown of physics?

from Malcolm MacCallum

A Relativity Workshop was held at Gregynog Hall of the University of Wales on September 1–3.

"God not only plays dice. He also sometimes throws the dice where they cannot be seen." This statement is made by S. W. Hawking (Cambridge University) in his recent work on black holes. About eighteen months ago he demonstrated that quantum processes could lead to the emission of thermal radiation from black holes, so evaporating them. This showed that the formal analogies between entropy and the area of the hole, and temperature and the surface gravity of the hole, are genuine identities. Now Hawking has circulated two preprints which develop this argument, which were discussed along with related papers at the workshop.

In the first he discusses the thermodynamics of black holes. He interprets the meaning of the entropy in terms of lost information about the initial state, proves that the second law of thermodynamics holds, and proceeds to argue, by considering a black hole in a box, that as a consequence of time-reversibility and ergodicity the emission from white holes (the time-reverses of black holes) must be thermal, and that hence black and white holes are indistinguishable.

In the second—"Fundamental Breakdown of Physics in Gravitational Collapse"—Hawking proves that the radiation has thermal statistics as well as spectrum, in agreement with independent work of L. Parker (University of Wisconsin) and R. M. Wald (University of Chicago). He argues that the random loss of information into the black hole implies the breakdown of S-matrix theory and that a density matrix formulation is all one can give. By considering further the white hole in a box he infers a 'Randomicity Principle' that singularities emit all possible configurations with equal probabilities, as pithily described above. Hawking asserts that this is necessitated by CPT invariance or by the non-existence of perpetual motion machines.

B. F. Schutz (University College, Cardiff), the organiser, opening the conference, pointed out that these two papers re-established the primacy of the thermodynamics. Various speakers emphasised the heavy dependence of

Hawking's arguments on the full applicability of standard thermodynamic results such as the meaning of entropy and the ergodicity theorem, and questioned the correctness of these assumptions. Schutz pointed out that application of Hawking's black hole calculations to white holes led to a burst of radiation with Rayleigh-Jeans spectrum at infinite temperature, resulting from particle creation from an initial vacuum. This might upset the thermal nature of any emission from within the hole itself. Schutz suggested some ways out of this difficulty, including the existence of a remnant black hole after the white hole explosion. C. J. S. Clarke (University of York) similarly suggested that a black hole evaporation must leave behind a naked singularity.

M. Perry (Cambridge University) presented some work on the modification of Hawking's picture to allow for strong interactions between the particles produced at high temperatures. Unless a very soft equation of state is used, the only consistent picture is that this is unimportant.

R. Penrose (Oxford University) expressed disquiet with the idea of black holes in boxes re-forming by the time-reverse of the evaporation process, which is important to Hawking's argument about equivalence with white holes. He also offered a modification of Hawking's proposed fluctuation mechanism for temporary destruction of the black hole, and various participants did back-of-envelope calculations to substantiate his point.

S. Fulling (King's College, London) and P. Candelas (Oxford University) gave talks on the technical aspects of quantum field theory in curved space-time, focusing on the definitions of the creation and annihilation operators and the vacuum state, and on the Feynman propagator. These talks explored, *inter alia*, the fact that incautious use of Rindler coordinates in flat space produces results inequivalent to the usual quantisation. Fulling showed that the treatment of the Hawking mechanism due to D. G. Boulware (University of Washington), which predicted no radiation, has failings of this kind.

The meeting was highly informal and many short contributions were made in discussion. The consensus seemed to be that the broad sweep of Hawking's ideas involved a great many interesting points, whose further examination was necessary. This will be an extensive programme since conceptual problems in general relativity, in thermodynamics and in quantum theory and their relation with general relativity, as well as difficult calculations, will be involved. The meeting helped greatly in clarifying some of the questions to be studied. \square

review article

Contacts with semi-insulators

H. K. Henisch* & C. Popescu†

Semiconductor contacts are of considerable practical interest because of their uses in rectification and photovoltaic energy conversion. Recently, however, they have become the focus of the critical controversy because of some unexpected behaviour on the part of contacts associated with semi-insulators.

SEMICONDUCTORS are believed to owe their very discovery to the observation of contact effects in the 1830s. The subject of semiconductor contacts has been of considerable interest ever since, often because contact properties themselves can be very useful, for example in the contexts of rectification and photovoltaic energy conversion¹. In such cases one aims to separate the contact properties from bulk (volume) properties, and to suppress the latter. At other times, when it is the bulk properties that one wishes to select, it turns out that most of these are experimentally "inaccessible" without the use of contacts in one form or another. The suppression of contact effects then becomes the principal aim but this is not necessarily a simple matter, nor indeed is there complete clarity on the criteria for success. Thus, whether wanted or unwanted, contacts (which must be regarded as abrupt heterojunctions) deserve attention and study. They have received a great deal of both in the past, chiefly in the context of technologically important semiconductors such as Ge and Si. Much less is known about effects associated with contacts to semi-insulators, that is materials with resistivities of the order of (say) 10^4 – 10^{10} Ω cm. This is now an active field of study in the context of which new insights have recently been gained.

All precise knowledge of contact effects begins, in principle, with an experiment of the kind shown in Fig. 1. By means of current-less potential probes, whether fixed or movable, the potential drop along a semiconducting bar is explored and compared with the potential difference across the two-terminal system as a whole. This procedure reveals the existence of voltage drops 'at' the contacts, which depend asymmetrically on the current density, as shown in Fig. 2. When this was discovered (on semiconducting sulphides) in the 1870s, it was realised that voltage drops cannot really occur at the interface planes between contacting materials, but must be across some regions of the specimen. Foreign contaminants suggested themselves as a source of the additional resistance, but none could be compellingly identified in that role. It became clear that if some "special region" were involved, it had to be made up of the parent material itself, though modified in some way to make it near-insulating. The explanation of the mystery came with the development of the Mott-Schottky potential barrier models of the 1938–42 period^{2,3}. These models explained not only the voltage drop at contacts but also the asymmetrical departures from Ohm's law associated with them (Fig. 2). These departures result from the presence of carrier concentration gradients which, in turn, imply diffusion currents, to which Ohm's law is in no way applicable. The departures from linearity

are asymmetrical, because the contact barrier is asymmetrically distorted by externally applied voltages, as shown schematically in Fig. 3. Typical barrier thicknesses range from 10^{-6} to 10^{-4} cm, depending on the nature of the surface and the purity of the semiconductor. For an appropriately simplified single-carrier system the carrier transport equation was easily solved, and a voltage-current relationship calculated. Refinements were later introduced to take account of image forces and hot carrier effects, but the model is still used today substantially in its original form. Whether it should be so used is another matter. Schottky himself pointed out that the barrier actually contains too few discrete (and, by assumption, randomly distributed) centres for the space charge to be treated as continuous, and an appropriate correction for this fact has never been devised. Moreover, the model assumes barrier heights greatly in excess of kT and thus applies only to high barriers. Similarly, its validity is limited to thick barriers, for which tunnelling processes can be ruled out. The last two assumptions limit the validity of the model to barriers of high resistance, and whereas no limitation is actually welcome, this particular one is less damaging than one might think because, in practice, we know so much more about contacts of high than of low resistance. This is so because very high voltages are not ordinarily applied to low resistance contacts, and under low voltages (that is voltages smaller than kT/e) all contacts behave almost linearly, as is obvious from Fig. 2. Such contacts may appear "ohmic" for practical purposes, but this does not mean that they are free from barriers (or carrier concentration gradients arising from other causes). Barriers may in fact be present, and would undoubtedly show

Fig. 1 Determination of contact voltages.

†On leave of absence from the Central Institute of Physics, Bucharest, Romania.

Fig. 2 V - I characteristic of metal-semiconductor contact.

themselves if higher voltages were applied. Such an experiment would, however, have to be carried out with very short voltage pulses, to prevent destruction of the system by heat. Contrary to popular belief, there is no simple relationship between the magnitude of a contact resistance and its linearity. Whether a contact is "ohmic" or not, that is whether it conforms to Ohm's law, thus becomes a relative assessment, and that is actually the only sense in which the term "ohmic" can be safely and unambiguously used.

Because of the experimental difficulties involved, low resistance (low barrier) contacts are rarely studied in a quantitative way. Moreover, they cannot be theoretically handled by the classical transport theory, but call for wave mechanical treatments along the lines of the Fowler-Nordheim analysis, modified by space charge considerations. Such treatments had been completely lacking, until the work of Gossick^{4,5}. "High" and "low" barriers are obviously limiting abstractions as, indeed, are "thick" and "thin" barriers, especially when we are dealing with non-rectangular energy contours of variable shape. The most general case is therefore highly complex and awaits the attention of some dedicated worker with an unflinching enthusiasm for modern computer techniques.

The above account assumes that contact and bulk resistances can always be clearly distinguished from one another, for example by an experiment of the kind shown in Fig. 1. This is equivalent to the assumption that the semiconductor material under a contact remains electronically unchanged by the presence of the current. It was precisely the breakdown of this assumption that led to the invention of the transistor. Bardeen and Bratton⁶ were exploring the field pattern in the neighbourhood of a point contact which was passing a current in the forward direction. They found that the material to a substantial depth under the contact behaved as if it had higher than normal

bulk conductivity. Additional charge carriers were evidently present in the affected region, but charge carriers of one sign could not be contemplated, because the resulting space charges would have been enormous. The effect could not, therefore, be explained on the basis of a single-carrier model, and in response to this difficulty the inventors of the transistor formulated the concept of minority carrier injection. The contention (since then amply confirmed) was that, at the contact and immediately below, the current is carried not by the majority carriers which predominate in the bulk, but by minority carriers. In n -type material, the injected carriers would thus be holes, present in (non-equilibrium) excess concentrations ΔP . These carriers drift and diffuse in the semiconductor as far as their "lifetime" will allow. Of course, their contribution to the current cannot actually "disappear"; in due course injected minority carriers recombine with resident majority carriers in a manner which ensures current continuity. Before the minority carriers have time to recombine, they attract (in media of relatively high conductivity) an excess ΔN of charge-compensating majority carriers into the injection region. The result is an excess of both types of carriers in a region which remains essentially neutral, and this accounts for the higher than normal conductivity. Figure 5a shows this situation. The magnitude of the increments ΔN and ΔP depends on the carrier lifetime, on the height of the contact barrier (relative to the band gap), and on the current density.

In due course it was found that minority carrier injection is only one out of four possible non-equilibrium processes which can be sustained by currents through semiconductor contacts, and are controlled by minority carriers. The others are minority carrier accumulation, exclusion (terms originally coined by P. C. Banbury) and extraction (see Fig. 4). For reasons which are outside the scope of this discussion, only one of these four effects, namely injection, has so far been shown to lend itself to practical applications, and that is why we have (in that sense) only one type of transistor. For the same reason, minority carrier injection is the only process considered here. In specific contexts, the non-equilibrium effects can be negligible, but that a contact should exhibit none of the four effects in greater or lesser degree is actually inconceivable. In the presence of a current, any discontinuity in the conductive properties must lead to the formation of a transition region, within which the carrier concentrations depart from equilibrium, and the current composition adjusts itself to the normal bulk mode. Thus, every contact is associated with contact effects, and we have learned a good deal (if not actually enough) about the design of contacts with specific properties.

Until recently, it was always assumed that the above non-equilibrium effects would be totally suppressed in materials of very short lifetime, but even this apparently self-evident expectation involves an internal conflict. Implicit in the above account is the assumption that the carrier lifetime τ_0 in the semiconductor is much greater than the dielectric relaxation time τ_D ("lifetime semiconductor"). It is this assumption which permits

Fig. 3 Rectification through asymmetric distortion of the contact barrier (shown for n -type material). *a*, In equilibrium; *b*, with a forward voltage applied; *c*, with a reverse voltage applied. Arrows denote electron flow. M, metal; SC, semiconductor.

Fig. 4 The four non-equilibrium effects which can result from current flow through a contact. n-Type semiconductor $\gamma_1 > \gamma_0$ injection; $\gamma_1 < \gamma_0$ exclusion; $\gamma_2 > \gamma_0$ extraction; $\gamma_2 < \gamma_0$ accumulation, where γ_0 is current composition rate. γ_0 (its value far from contacts) $= I_p/I$, where I_p = current carried by minority carriers.

minority carrier space charges to be neutralised by an influx of majority carriers, before carriers recombine. As long as $\tau_D \ll \tau_0$, the supply of compensating charges is always plentiful. If the lifetime τ_0 were to approach zero, however, this inequality could not be maintained, even in the relatively well conducting transistor materials. In materials of higher resistivity the situation is generally reversed, that is $\tau_D \gg \tau_0$, and neutralisation becomes very difficult.

The changes which the assumption $\tau_D > \tau_0$ implies in our picture of contact injection were not appreciated until recent years, when attention was drawn to them by van Roosbroeck and Casey⁷⁻⁹. In so doing, they opened a completely new field of inquiry. In particular, van Roosbroeck pointed out that minority carrier injection into a semi-insulator (a "relaxation semiconductor") would lead to majority carrier depletion ($\Delta n < 0$), and not to an excess of both carriers, as it does in the conventional lifetime semiconductor. In turn, the majority carrier depletion was expected to lead to a higher than normal total resistance, again in contrast to the lifetime case in which the total resistance of the system is lowered by injection. It was also predicted that the current-voltage relationship of such a system would be sublinear, and that the depletion region would spread throughout most or all of the available material. This spread was expected to have a peculiar and important consequence: it would invalidate one of the most popular tests for contact effects, namely the proportionality between specimen resistance and specimen thickness (bearing in mind that measurements on semi-insulators cannot be performed in the manner suggested by Fig. 1, but only on two-terminal thin film systems, without potential probes). The model suggested that, in relaxation semiconductors, this proportionality would be essentially

maintained in spite of the presence of minority carrier injection. The resistance determined in this way would, however, be a good deal higher than that calculated from the dimensions and the undisturbed bulk resistivity, and to that extent a totally misleading result could be obtained.

Of course, majority carrier depletion can be expected to have an important role only as long as the material contains a significant number of majority carriers to deplete. In really wide-gap insulators, there are virtually none, and all injection (whether of majority or minority carriers) then gives rise to purely space charge controlled conduction processes, of the kind analysed and discussed by Lampert and Mark⁹. These processes give rise to a proportionality between (current) and (voltage)², equivalent to Child's law in a vacuum, but different because of the limited mean free path of carriers in a solid. In what follows, we are concerned with poorly conducting materials in which, however, resident carriers still play an important part.

The startling van Roosbroeck predictions were duly challenged in the literature, and even the notion of majority carrier depletion as such was thrown into serious doubt. One of the difficulties is that the two-carrier transport equations cannot be explicitly solved. "Simplifying assumptions" can certainly be introduced, but whether these distort the picture or are truly helpful can be reliably assessed only by comparison with the full solutions, and these must come from the computer. They have only recently become available (refs 10 and 11 and C.P. and H.K.H., unpublished), and their general significance may be outlined as follows.

The relationships can be best understood by comparison with the more familiar lifetime case. Figure 5 gives computed contours for the additional carrier concentrations ΔP and ΔN , as well as the field, as a function of distance from the injecting interface. Figure 5a and b are for the same normalised current density, the only difference being the ratio τ_D/τ_0 (or, somewhat more accurately, τ_{Dn}/τ_0 , where τ_{Dn} is the relaxation time arising from majority carriers alone). It will be seen that the majority carriers are indeed strongly depleted (ΔN negative) under the contact in the relaxation case, as van Roosbroeck had suggested. The disturbance extends over a number of Debye lengths which, in a semi-insulator, can amount to an appreciable depth. The depletion is virtually complete and, accordingly, the recombination of injected minority carriers is inhibited in this region. It therefore takes place in "recombination front" (where ΔN has its sharp gradient). It can be shown that the total carrier concentration $N+P$ is also depleted over a certain distance and has a well defined minimum. This minimum falls, however, within a region in which the diffusion currents are high, and in such a region carrier concentrations do not control the current; concentration gradients do. The minimum of $N+P$

Fig. 5 Consequences of minority carrier injection into n-type material. a, Lifetime semiconductor ($\tau_D/\tau_0 \leq 1$); b, relaxation semiconductor ($\tau_{Dn}/\tau_0 \geq 1$), for same (normalised) current density.

Fig. 6 Carrier concentration and field contours for minority carrier injection into a relaxation semiconductor containing traps.

does not, therefore, govern the resistance of the system as a whole. Assuming bimolecular recombination and equal electron and hole mobilities, the total resistance can be shown to be smaller than that expected from the bulk resistivity, in spite of the majority carrier depletion. The presence of diffusion currents contributes to this fact, but the physical picture is clear enough even without them. The resistance is actually determined by two opposing tendencies, of which the first wins: (1) the high concentration of injected minority carriers, and (2) the depletion of resident majority carriers.

It is interesting to consider the behaviour of such an injection system under illumination¹¹. In the presence of radiation, the space charge system is modified; accordingly, recovery (when the radiation ceases) involves not only the recombination of excess carriers but a space charge movement. This means that the time constant of photoconductive decay is not a pure carrier lifetime, but a complex mixture of recombination and relaxation effects, involving τ_D as well as τ_o . As a consequence, carrier lifetimes cannot ordinarily be determined from photoconductive decay experiments in the relaxation case. The calculations of Fig. 5 refer explicitly to the contacts of "unit injection ratio", that is contacts for which the entire current is made up of minority carriers at the metal-semiconductor interface. In terms of a semi-infinite n-type semiconductor, this means $J_o = J_{po} = J_{\infty}$, where J_{∞} , the current far from the contact, is, of course, carried by electrons. Quantitatively, the available results are limited to their case, but *mutatis mutandis*, the model applies also to lower injection ratios. Of course, all injection effects are then diminished.

If the above (idealised) model yields only lower than normal resistances, as it does, there remains the interesting question of whether higher than normal resistances can ever be envisaged, as originally suggested by van Roosbroeck. A search for such forms of behaviour must inevitably turn to systems of a more realistic (albeit more complicated) kind. To be realistic, a model must include some consideration of trapping processes, which are almost universally characteristic of semi-insulating and insulating materials. Trapping has two aspects: (1) it involves recombination through centres, implying a carrier lifetime which is not constant, as assumed above, but dependent on injection level, and (2) it involves space charge storage. Of these, the second is actually the more potent factor, as recent calculations (C.P. and H.K.H., unpublished) have shown. To understand the role of the traps, it is convenient to refer again to Fig. 5a, even though these particular contours apply to trap-free conditions in a normal lifetime semiconductor. It will be seen that over most of the injection region neutrality prevails, but close to $X = 0$ there is an imbalance, which creates an electric

field. This field actually serves two distinct purposes, both designed to provide electrons in sufficient numbers to satisfy the recombination needs: (1) the field supports electron drift towards the injecting plane, and (2) it opposes electron diffusion under the prevailing (negative) concentration gradient. Because of (2), the field is locally greater than that required to sustain the electron recombination current as such. The greater the concentration gradient, the greater would the field in this region have to be. These relationships are general, but they have a particularly important bearing on the case with traps.

In n-type material trapping states (assumed for simplicity to be located half way across the forbidden band and in equal communication with electrons and holes), would change their occupancy in response to any non-equilibrium situation; in other words, these traps could trap electrons or holes, depending on the relative concentrations. It is then an easy matter to show, on the basis of quite conventional Shockley-Read considerations, that the trap response to excess holes is much more sensitive than that to excess electrons; the traps are overwhelmingly hole traps (as long as there are holes to trap). A very small unbalance in the equilibrium trap occupancy is sufficient to produce enormous fields, and if there were no compensating mechanism, the positive space charge density would soon become quite excessive for the maintenance of current continuity. There is, however, a compensating mechanism, namely the attraction of majority carriers from the bulk material (Fig. 6). Accordingly, an excess ΔN of free electrons appears in the injection region. We then have $\Delta N > \Delta P$, the charge difference being made up (almost everywhere except close to $X = 0$) by the trapped (immobile) holes. This happens in the relaxation case as well as the lifetime case. Indeed the presence of traps can change the situation from a relaxation regime to a lifetime regime. The appropriate criterion is then no longer τ_{Dn}/τ_o , but $\tau_{Dn}/\tau_o (M_o + 1)$, where M_o is the (normalised) trap concentration. In the trap-free case, the field has its highest value in the bulk, as Fig. 5 shows, but when traps are present in sufficient concentration, the maximum field is in the disturbed region (Fig. 6). This means that the total resistance is indeed higher than that expected from the bulk resistivity, though for reasons very different than those originally envisaged by relaxation semiconductor models. The emphasis here is not on the fact that we are dealing with injection into a relaxation semiconductor but on the fact that we are dealing with injection into a material containing large numbers of traps. That is when the negative gradient of majority carriers appears, even when the carrier lifetime is shorter than the relaxation time. In otherwise comparable conditions, lifetime semiconductors can be shown to exhibit similar and, indeed, more pronounced resistance enhancement effects. In Fig. 6, the field is at its maximum necessarily where the concentration gradient is at its maximum (and not within a majority carrier depletion region). The general conditions of current continuity are maintained. Of course, high carrier lifetime coupled with high trap density do not ordinarily go together, but in good photoconductors they do. Moreover, recent observations on gallium arsenide along these lines by Ilegems and Queisser of Bell Telephone Laboratories may refer to just such a combination of parameters, and the internal resistance of many junction-type solar cells must depend on these considerations.

One of the interesting aspects of the matter is the way in which a challenge of long cherished assumptions has led to completely unforeseen forms of behaviour. Moreover, what has been done so far is only a beginning; virtually every kind of electric, photoelectric and galvanomagnetic measurement procedure applied to semi-insulators is due for re-examination, a process which will no doubt take several years, and which may lead to new applications as well as a new understanding of transport processes.

Limits to energy release and utilisation from chemical fuels

S. A. Lloyd & F. J. Weinberg

Imperial College, London SW7, UK

New combustors effectively abolish limits of flammability and extend the concept of what is a fuel. By burning very lean mixtures they also minimise pollution and irretrievable energy losses during conversion. The theoretical saving is more than double the proportion currently contributed by all nuclear and other 'non-combustion' sources.

PREVIOUS communications^{1,2} re-examined combustion strategies in response to energy shortages and described one particular burner³ for mixtures of very low heat content. This was based on massive heat recirculation between products and reactants, without simultaneous dilution by recycling products. Quite small models enabled mixtures to be burnt which corresponded in heat content to only one-third of the normal "limit of flammability" and this at flow rates two orders of magnitude in excess of the burning velocity of limit mixtures.

In terms of the conventional definition of a fuel as "something that will burn" such devices evidently extend the definition of "what is a fuel?" Quite apart from the various sources of very lean mixtures which could be burned by such methods³, (for example, ventilation air from mines, waste gases from various industrial and fermentation processes) many materials potentially capable of exothermic reaction are not now regarded as fuels because they contain a large proportion of inerts. Although brandy is generally recognised as a fuel in a combustion as well as a metabolic sense, beer, for example, would probably be considered so only in the latter sense. More seriously, methane diluted with 90% of inert gases would not previously have been rated as a fuel because it would not burn in air—that is, the stoichiometric mixture it would produce with air, if it were to burn as a diffusion flame, would lie below the normal limit of flammability.

In the majority of applications the question is not only "what can we burn?" but also "how much of the energy released can we usefully abstract?" There are, in fact, quite a few exceptions to this in the realm of the combustion of very lean mixtures because it is often desirable simply to burn up noxious pollutants to more innocuous products. In the present—and future—climate of energy shortages, however, the thermodynamic potential at which combustion energy can be utilised must always be a major consideration.

Since an improvement of energy utilisation from combustion of only 12.5% could, at present, replace all nuclear and other energy sources, we feel, generally, that insufficient attention is being paid to these problems. Accordingly, we have investigated

the absolute minimum heat contents at which stable burning can be maintained using the principle of recirculatory burning and the thermodynamics of conversion of the heat released from such lean mixtures.

Minimum heat content for combustion

The geometry of the "Swiss roll" burner³ is most readily appreciated by reference to a diagram of its cross-section (Fig. 1a). This is purely schematic: the depth (perpendicular to the diagram), the width and number of turns, the size, nature, and packing of the central combustion chamber, as well as the material of construction, are all variable. Since the maximum temperature attained in a combustion zone (see Fig. 2a) is determined by the amount of heat transfer, the reaction rate and thus the heat content of the 'minimum combustible' mixture are all functions of these geometric variables.

In the series of experiments designed to establish the leanest mixture which could be burnt, no heat was abstracted. The main sequence of experiments was carried out using methane as fuel, though a few tests were carried out on hydrogen, propane and ethyl alcohol. The burners were constructed of Inconel 600 strip, the width, number of turns of the spiral, and insulation being progressively increased to minimise heat losses as the fuel content was decreased. Thermocouples sealed into the spiral recorded the five temperatures in the positions shown in Fig. 2a; the initial, final, maximum just before and just after the combustor being denoted by subscripts 0, f, m, 1 and 2 respectively. Variation of flow velocity for each set of conditions produced

Fig. 1 Schematic of spiral cross section. a, Simple burner; b, second channel for processing another reactant.

stability loops similar to those observed previously³. If there were no heat losses, first law considerations demand that

$$T_m = T_1 + q = T_2 = T_0 + (T_2 - T_1) + q$$

where q is the temperature rise across the combustion zone, also equal to $(T_1 - T_0)$, and $(T_1 - T_0) = (T_2 - T_1)$. Absence of dissociation at these low temperatures, constant specific heat and a heat of reaction independent of temperature are assumed throughout for these highly diluted mixtures. In the present experiments there were always some heat losses (though it is possible to eliminate them almost completely as we show later) and errors in thermocouple readings include radiation exchange with the walls as well as catalysis, particularly for T_1 , at low fuel concentrations. Labelling heat losses as shown in Fig. 2a, the above equations become:

$$\begin{aligned} T_m &= T_1 + q - L_2 = T_2 + L_3 \\ &= T_0 + (T_2 - T_1) + q - (L_1 + L_2 + L_4) \end{aligned}$$

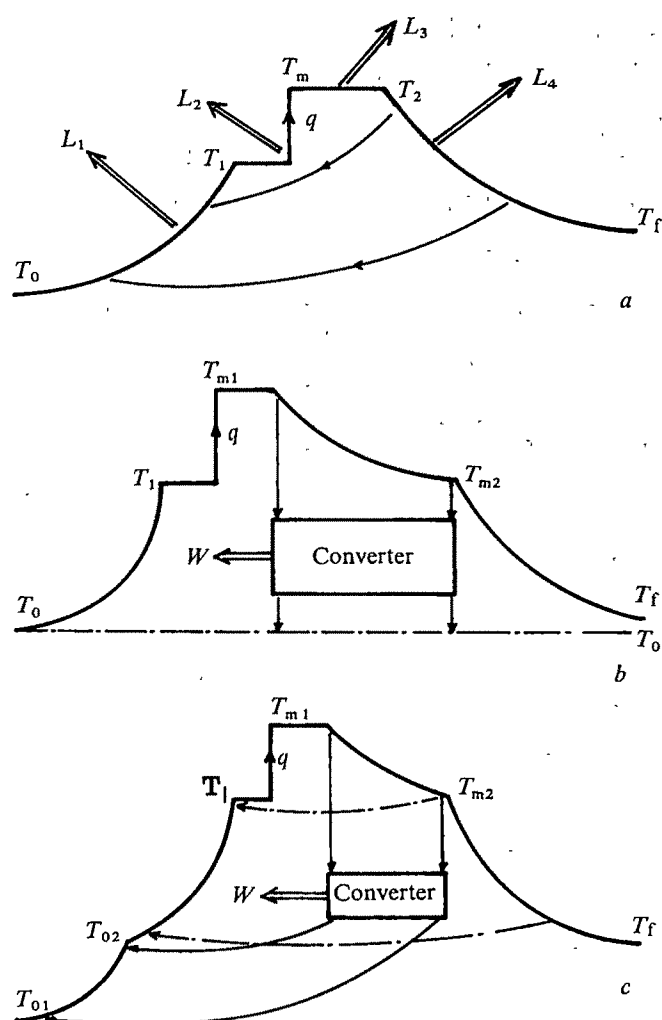

where

$$L_1 + L_2 + L_3 + L_4 = q - T_1 + T_0$$

and

$$L_1 + L_4 = (T_2 - T_1) - (T_1 - T_0)$$

Fig. 2 Temperature schemes without (a) and with (b,c) heat abstraction.

These, together with the measured values, were used to establish criteria governing stability limits.

The richest mixture studied was well below the flammability limit (5.3% methane in air) at 3.7% methane. Increasing the number of turns on the spiral for a given width of strip at first enabled leaner mixtures to be burnt. Plotting the leanest fuel concentration against the number of turns resulted in, approximately, rectangular hyperbolae—the decrease levelling off as sideways losses became controlling. Increasing the width of the strip and adding insulation caused the decrease in limiting fuel concentration to be resumed. We did not continue this progression to much below methane concentrations of 1%.

The salient feature which correlated the various temperature results (to be published in detail elsewhere) was extremely simple: the temperature in the reaction zone at the limit remained constant, within experimental error. For methane, this temperature is approximately 1,400 K. The explanation is thought to be that the limiting reaction rate is constant and, because of the high activation energy, very much more dependent on temperature than on composition. Using an overall activation energy⁷ of 268 kJ mol⁻¹, a change in the reactant concentration from 1.0 to 0.5% would correspond to a temperature rise of only 45 K.

Results obtained by Smith⁴ in a study of the temperature dependence of limits of flammability can be interpreted similarly. Although the mixtures were preheated by an external source and prereaction did not enable him to go leaner than 3.4% methane, the final flame temperature which can be calculated from the sum of his chemical and thermal enthalpies is in fact remarkably close to ours, at 1,430 K. Our much leaner mixtures burn without external intervention at much the same temperature and our extrapolation of this relationship would intersect the 'pure air' axis at about that temperature.

Having gone 82% of the way from the normal limit of flammability towards pure air, we discontinued the experiments and concluded that for all practical purposes there are no limits of flammability for combustion, when heat recirculation is not accompanied by simultaneous dilution of the reactants with products. In practice, sideways heat losses can be abolished altogether by turning the 'Swiss roll' into a torus. For materials which are not sufficiently flexible, or do not pass through a plastic stage during manufacture (as do some ceramics) an assembly of slices with non-parallel sides may be used. Such a configuration is of course not designed to withdraw heat at the highest temperature and, with a sufficient number of turns of the spiral, the product enthalpy flow is the only heat exit. In these conditions, however, anything capable of even marginally exothermic reactions becomes a potential fuel. The final temperature corresponding to the leanest mixture we burnt was approximately 225 K and, on the above activation energy argument, 0.22% methane should be possible before the temperature in the reaction zone would begin to damage our construction material.

Possible applications in which heat abstraction at the maximum temperature is not required include room heating, allowing the product to escape directly into the room. The saturated vapour pressure of conventional fuels is quite sufficient to enable air saturated with the fuel at room temperature to be burnt without previous atomisation or pumping and the combustion temperature ensures both complete combustion and negligible formation of CO and oxides of N₂. For burning up certain industrial waste gases and pollutants, the residual gas temperature may only be sufficient to provide enough buoyancy for dispersal through a stack. Among other proposals is the humidification, heating and sterilisation of hospital atmospheres by injecting a small proportion of hydrogen before passage through the burner.

Thermodynamic efficiency

When considering heat abstraction at the maximum temperature, for example, for conversion into other forms of energy, the conclusions are no less surprising than the finding that such

burners manifest effectively no limits of flammability. The striking conclusion is that, even starting from prime fuels, a higher conversion efficiency can result if the fuel is first diluted with a great excess of air.

There is a great variety of possible schemes for incorporating a converter, or heat engine, into the heat recycle. Figure 2b and c shows two examples: the former rejecting to an infinite (isothermal) heat sink and the latter to the heat exchanger inlet. A cursory treatment⁵ of the theory is somewhat inadequate and a more detailed account is being published elsewhere⁶. Although the overall efficiency is highest when the system shown in Fig. 2b is used with a thermodynamically efficient converter, for inefficient (for example, thermionic) converters it may be advantageous to use a different configuration. One possible reason is the large electrode area made available if parts of the spiral are used in that capacity³. For an inefficient converter, this advantage can outweigh the disadvantage of the rising temperature of the heat sink, particularly where the efficiency is overwhelmingly dependent on the temperature at which electrons are emitted⁶.

In this instance, however, we are concerned with the maximum amount (hence also pumping and other losses are neglected) of energy available. If we postulate converters consisting of a succession of elemental Carnot cycles the efficiencies corresponding to Fig. 2b and c can be shown⁵ to be

$$1 - [T_0/(T_{m1} - T_{m2})] \ln(T_{m1}/T_{m2})$$

and

$$1 - T_{02}/T_{m1} = 1 - T_{01}/T_{m2}$$

respectively. The nearest practical approach to these idealisations would be represented by two Stirling motors, their 'hot ends' contacting the sides of the combustion chamber in the centre of the 'Swiss Roll', their 'cold ends' being exposed to ambient conditions or, in the case shown in Fig. 2c, to a regenerator from which the reactants enter the spiral. The sides of the spiral would be insulated. In these conditions, the maximum value of temperature, T_{m1} , and thus of the efficiency, is entirely limited by the melting point of the confining material used and totally independent of the heat of reaction, since the heat recycle enables any temperature up to that maximum to be reached. (But for this restriction—and the effects of high temperature on dissociation and q —we could attain 100% efficiency.) As T_m tends towards infinity, the heat rejection tends towards zero. If we now allow the converter to use all the heat of reaction—that is, if we make the heat exchanger long enough to transfer the required amount of heat on a temperature differential which is negligible by comparison with that across the reaction zone—the two expressions for efficiency become

$$1 - (T_0/q) \ln[T_m/(T_m - q)] \text{ and } 1 - T_0/(T_m - q).$$

It follows that the efficiency increases as the temperature rise across the combustion zone falls, attaining the Carnot value $1 - T_0/T_m$ as q tends towards zero. The initially surprising result that efficiency can actually be improved by diluting the fuel, and making up the maximum temperature by recirculation, is simply due to the smaller temperature fall during the abstraction of the heat of combustion. The trend to the Carnot value in the first efficiency expression becomes more obvious on writing $\ln[T_m/(T_m - q)]$ as $\ln[1 + q/(T_m - q)]$ and expanding the logarithm for small values of q , whereupon the first expression reduces to the second.

The startling consequences become apparent on introducing realistic numerical values. Taking the maximum temperature at which the converter walls would melt, or oxidise, as the modest value of 1,500 K, the Carnot efficiency to which the above expressions tend at increasing dilution, is 80%. For the leanest mixtures burnt in the present work, $q/(T_m - q) \approx 0.18$. The corresponding efficiencies for the two systems are as high

as 78.3% and 76.5%, respectively. Using a richer mixture—such as would produce a final flame temperature of 1,500 K without recirculation—would give a maximum efficiency (external heat sink) of less than 60%. Thus the gain obtained from dilution and recirculation is equivalent to burning approximately one-third more fuel. On a global scale, this would provide more than double the requirement for replacing all nuclear contributions. Yet it takes no account of the difficulty of stabilising a flame of even that final temperature by conventional means. 1,500 K would be considered a very low flame temperature and it is the need for flame stability which is generally responsible for our using near-stoichiometric mixtures whose product gases, having generated oxides of nitrogen at these high temperatures, then have to be cooled down before they become acceptable to the converter.

Fig. 3 Radiant emission at maximum temperature.

This argument clearly applies only to systems limited by the melting point of walls. Where the hot gas is expanded while confined by cooled surfaces, other limitations, due to quenching, and so on, apply. As 1,500 K already corresponds to a Carnot efficiency of 80%, comparison with efficiencies attained in practice may cause us to reconsider the need for high combustion temperatures.

Similar considerations apply to abstracting heat at the maximum temperature, T_m , for purposes other than energy conversion (as distinct from using only the enthalpy of the product gases, at T_f , which we discussed earlier). For heat transfer by radiation, for example, using the temperature at the top of the 'thermal dam' is essential. Figure 3 illustrates this for a system fitted with a quartz window, the beam being made visible by scattering from smoke introduced in the vicinity and by the use of a 'luminous mantle' in the combustion chamber to increase the visible component of the radiation.

Figure 1b shows a four start spiral which was constructed for processing a fluid at the high temperature. Of the two neighbouring channels, one carries the combustion gases as before and the other the gas which, for example, undergoes an endothermic reaction at the high temperature. This may be used for the production of a higher grade fuel from the heat released by a lean mixture. The endothermic water-gas reaction, or reforming, provide simple examples of producing a higher specific calorific value from a low one and retrieving the unused thermal

energy. Although the heat flows are coupled, the mass flow rates in the two streams are of course entirely independent.

In the processing of solids, conveyance along spiral channels would be difficult and a more conventional furnace geometry is obtained by passing the furnace tunnel axially through a deep spiral. So long as heat carried away by the material processed and lost by conduction along the refractory tube is minimised, the essential principle of decoupling the heat flow from that of the product gases (which again leave through the spiral) can be maintained. Solid and liquid fuels which pyrolyse pose a similar problem. In this instance the most versatile arrangement is based on a fluidised bed in the combustion chamber, the surrounding spiral carrying only the incoming air and the departing product gases, the fuel being fed directly into the combustor. We are of course considering very low grade fuels—including various forms of refuse—so that strictures on the use of diffusion flames³ do not apply. Quite apart from the limitations imposed on maximum mean temperatures, maximum local temperatures are limited by the high diluent content of the stoichiometric mixtures which occur in the inter-diffusion zones.

Conclusions

Burners and combustion equipment generally have always been exceedingly simple, and given the availability of prime fuels and lack of concern about pollution, there is no reason why they should not have been. We have shown that such a minor escalation in complexity (in comparison with, for example, energy release by nuclear reactions) as the use of massive heat recirculation will greatly widen the limits to the release and utilisation of energy. It effectively abolishes limits of flammability, makes anything that is capable of exothermic reaction into a "fuel" and confines the limitations in energy conversion largely to those of the converter itself.

Strained mixed-cluster model for glass structure

C. H. L. Goodman

Standard Telecommunication Laboratories Ltd, London Road, Harlow, Essex, UK

Many features of glass behaviour can be explained by a new approach to glass structure based on two ideas. First, glass-forming melts generate 'clusters' of structurally non-related polymorphs which associate on cooling but cannot nucleate, and second, inter-cluster thermal strain can be relieved by subsequent 'plating-out' of modifier impurities.

GLASSES comprise a wide class of solids ranging from the familiar soda-lime-silica window glasses to relatively little known arsenide and phosphide based semiconducting materials¹⁻³. Perhaps the one feature all glasses have in common, and which defines an amorphous material as a glass, is a 'glass temperature', T_g . Above this temperature a glass behaves as a supercooled liquid, with a finite though possibly large viscosity; below T_g a glass is a solid, and, at least at low stresses, behaves elastically. T_g can be somewhat varied by cooling rate, and is associated with discontinuities in the temperature variation of many physical parameters, for example thermal expansion, specific heat and refractive index. Any convincing model of glass should be able to explain such behaviour.

Glasses usually show a number of other features, not all of which are readily understood on the basis of one or other of the generally accepted approaches to understanding glass: the network and microcrystalline models (for description see refs 4-7). Thus, there is evidence from X-ray diffraction studies that the short range order in glasses is similar to that in corresponding crystalline solids⁸⁻¹⁰, a conclusion echoed by Raman and backed up by infrared phonon studies (see, for example, refs 11 and 12). There is also evidence from small-angle X-ray scattering of 'micro-heterogeneities' in glass on the 20-Å scale¹³. Even more strikingly, changes in thermal expansion at temperatures corresponding to solid-state polymorphic transitions in related crystalline phases have been found in some oxide glasses, for example, in vanadium phosphate¹⁴ and even in pure silica (C. F. Drake, personal

communication). Such behaviour is of course easy to understand on the basis of a microcrystalline model of glass. What is less easy to understand in these terms, however, is the effect of adding 'impurities' on the viscosity, workability and recrystallisation characteristics of oxide glasses. This, of course, is the basis of the powerful semiempirical techniques developed in the glass industry for preparing 'good' glass: the complex compositions, with some constituents only at a concentration of about 1%, are not used just because only impure raw materials are available at an economic cost, but because they have a real effect, particularly on devitrification properties. A 'good' glass has a shallow viscosity-temperature characteristic and remains workable over a large range of temperature; it most certainly does not recrystallise. It is here that the network model seems particularly applicable, which may account for its almost universal adoption in the glass industry.

Could these two models be unified in some way to give a more general explanation of the properties of glass? The unconventional but simple approach outlined here does seem to suggest a means of achieving this. One point seems of particular relevance: a surprisingly large number of the systems which form glasses have as a major (sometimes the only) constituent a material that exists in two or more polymorphic forms which only differ slightly in free energy. Silica, as an obvious example, is found as quartz, cristobalite and tridymite (and in a number of other less wellknown forms too), but polymorphism is also found with BeF_2 , PbO , As_2O_3 , TiO_2 , selenium, sulphur and CdP_2 , to name several materials of interest in the context of glass formation. Could this polymorphism be a necessary condition for a material to be a glass former? Consider a melt of such a polymorphic material being slowly cooled. At some temperature, associations of the constituent atoms will grow into 'flicker-clusters', incipient nuclei of all possible polymorphs (any significant difference in free energy, of perhaps more than 5 kT, or about 0.1 eV at 1,000 K, would be expected to reduce greatly the contribution of the phase with higher free energy, although

bulk free energies may only be a rough guide to the situation with such small quasi-crystallites). The existence of flicker-clusters in liquids near their freezing point is well established; their formation for example, is the reason for the maximum density of water occurring at 4 °C (ref. 15).

The behaviour of such a system with two or more distinct types of flicker-cluster does not, however, seem to have been considered previously. I suggest that on progressively lowering the temperature such a 'mix' would not behave like the melt of a solid which has only one modification, and that it would be difficult for the clusters to grow to the critical size for nucleation. Instead bonds between clusters with different structure and at random mutual orientation would, initially, continuously form and break, the tendency for their forming increasing as temperature was reduced. The resulting 'mixed-cluster associations' could, presumably, greatly exceed the critical size for nucleation for a single phase cluster without passing the surface energy determined maximum in free energy beyond which runaway crystallisation would normally occur. (Such a situation would give a melt in which viscosity would be expected to increase markedly as temperature fell.) Given this, a temperature would be reached at which a permanent, continuous, bonded network would be set up between mixed clusters, leaving much of the boundaries of the clusters non-bonded and with the material between them still 'liquid-like', even though the system as a whole would have now 'locked up solid', a rigid rather than a viscous material having come into being. Presumably this situation corresponds to some kind of percolation theory limit. It would of course also correspond to T_g . In addition, it is clear from this picture that slow cooling would give rise to a better accommodated continuous network of this kind than fast cooling, leading to just the behaviour found experimentally with T_g in terms of density, refractive index and so on.

An objection to this could be that if two types of cluster were present, A and B, then A-A and B-B contacts could occur as readily as the A-B type discussed above and would tend to lead to nucleation. The important point is, however, that the occurrence of A-B random bonding would hinder and eventually suppress subsequent A-A or B-B epitaxial contacts, which are what are required to reduce surface free energy.

Consider what happens on still further cooling. The liquid and presumably relatively mobile material would remain within the rigid mixed cluster framework gradually crystallising out, but with progressively more distorted bonding arrangement as cluster-cluster boundaries and voids (due largely to thermal contraction) are formed. There would, however, be a crucial further effect operating at the same time. Since the two (or more) cluster-phases would have different crystal structure symmetries, and would be bonded together with more or less random orientation, there must be thermal contraction mismatch between them. This would give rise to progressively increasing strain on cooling which would tend to increase the free energy of the system, making it increasingly unstable with respect to a more normally crystalline variant. (This term then might be particularly important in driving towards devitrification of a glass even above T_g .) It is here that I would suggest that the liquid material bonding out on to mixed clusters is important. Particularly if impurity atoms of correct size were present ('modifiers'), these would grow on to the cluster surfaces or associate at cluster-cluster boundaries in such a way as to reduce the strain contribution to the free energy and also, presumably, the entropy of the system. This, then, qualitatively explains the importance of small additions of specific impurities in stabilising the glassy state. This mechanism, incidentally, is in marked contrast with one put forward by Demishev¹⁶ who postulated microstresses between "an ordered phase" and "disordered material" due to differences in the thermal expansion coefficients of the two kinds of material, which coincide at T_g .

This phenomenological picture of how a glass forms suggests some interesting questions and predictions:

(1) The existence of liquid material with high atomic mobility

below T_g (albeit on an extremely small scale) should be amenable to direct verification by means of motional narrowing of nuclear magnetic resonance if a suitable isotope were available (¹¹B in borate glasses?), although presumably a sensitive apparatus might be needed since only a small proportion of the material would be expected to be involved.

(2) The mixed-cluster model also suggests that immediately below T_g a glass is very like a liquid-filled zeolite, the liquid being held in a system of small interconnecting channels, and with a very large solid surface in contact with it. Interesting effects of ion exchange and diffusional transport should be possible. This view is consistent with the known and highly important "gettering action" of glass films on the surface of silicon semiconductor devices.

(3) Perhaps on the basis of intuition more than argument, it may be possible in a particularly favourable case of glass-forming material and strain-relieving impurities to obtain a system with a lower free energy than any corresponding combination of macrocrystalline phases, that is a glass might be more stable than crystalline material—an almost heretical suggestion but worth further investigation.

(4) If more than the optimum amount of strain-relieving impurity were present in a glass system, the glass would become less stable, simply because there would be a tendency for a new phase to form in the now relatively thick layer of "extra-cluster material" which compositionally would be different from the clusters. If, however, this itself has suitable polymorphs a new mixed cluster system could arise, and still further addition of impurity could restabilise the system. This may offer a generalised explanation for the not uncommon occurrence of compositional systems which show broad glass-making fields, with varying glass stability, for example in the alkali silicates. The important new point here is that in such systems the glass former can be an intermediate compound rather than having to be an end member.

(5) If, as seems possible, the mechanism of strain relief by "plating out" from residual liquid could be a selective process operating not far from equilibrium, this may lead to an explanation of at least the low temperature behaviour summarised under the heading of "the mixed alkali effect" in silicate glasses¹⁷. The simultaneous presence in the liquid of two different-sized alkali atoms would then be expected to lead to a better packed and strain-relieved structure than either could give separately (for example, spheres of two different sizes can pack to fill space more efficiently than a single size of sphere) and thus a denser, more strongly bonded, higher refractive index glass. Such a structure would also account for the observed reduction in alkali diffusion rate in mixed alkali glasses.

(6) The case of vitreous silica is of particular interest. Detailed radial distribution function analyses by Konnerth and Karle^{8,9} showed the presence of tridymite-like quasi-crystallites perhaps 20 Å across and gave some indication that cristobalite-like material may also be present. As already noted, work in these laboratories by Drake (C. F. Drake, personal communication), using a sensitive dilatometer of his own design, has indicated changes in the slope of the thermal expansion curve of silica (from a variety of sources) which have been persuasively identified as associated with α - β transitions in quasi-crystallites of cristobalite and quartz. There is evidence, therefore, that vitreous silica contains at least three types of cluster. Now Cohen and Roy^{18,19} found that the density of vitreous silica is affected irreversibly by the application of pressures of more than 2×10^9 Pa. This can be interpreted on the present model as due to quasi-crystallites of the least stable phase, tridymite, going over to a more dense coesite-like structure. (The quartz-coesite transition is near 3×10^9 Pa (ref. 20) for bulk material; for tridymite a somewhat lower transition pressure would be expected.) If so, a Konnerth and Karle type RDF analysis of such densified material should be very different to that which was found for normal vitreous silica. At a sufficiently high pressure of course all quasi-crystallites would become transformed to rutile-like stishovite²¹ and recrystallise-

tion should occur immediately since no "two-or-more-cluster-phase-system" would be in question. Cohen and Roy^{18,19} in fact mention just such behaviour for GeO₂ glass, which would be expected to transform into a rutile-like structure at a lower pressure than for the case of SiO₂. The role of shear in such transformations²² does, however, require further investigation.

(7) It should be possible to distinguish between amorphous solids and those which might, potentially at least, be stabilised as glasses. Amorphous silicon and germanium, for example, can probably not be stabilised, since there seem to be no alternative crystal structures within a reasonable energy range, judging from the very high pressures and compressions required to bring about any phase transformation²³. It might, however, be argued, if the two-polymorph idea is correct, that quenching a germanium melt at a pressure sufficiently high for the freezing point to lie near the phase boundary between (metallic) tetragonal and (semiconducting) diamond type phases could perhaps give rise to a glass. More interesting possibly, is the case of carbon, where at 1 atm pressure ($\sim 10^6$ Pa) graphite and diamond phases differ in free energy by about 500 cal mol⁻¹ (~ 0.03 eV). This suggests that it may be possible to quench liquid carbon to give a glass. Could this be stabilised by transition metals such as iron? Is there any evidence of high viscosity due to graphite-diamond quasi-crystallite cluster formation in the "solvent catalyst" melts used for diamond synthesis, whose mode of action is still not too well explained?²⁴

It also seems likely that where two polymorphs are closely related in structure (for example wurtzite and zinc blende) and have not only the same coordination but differ solely in stacking (so that epitaxial relationship is possible), then the suppression of nucleation described above would be much less likely to occur. (In this context the findings that cristobalite²⁶ and tridymite (J. H. Konnert and J. Karle, personal communication) do not have the simple structures previously assumed to be zinc blende and wurtzite analogues are highly relevant.) For this reason, then, amorphous III-V and II-VI compounds, much like silicon and germanium, should not form glasses. Some reservation may be needed here in that glasses have been made from the related ternary chalcopyrite compounds CdGeAs₂ and CdGeP₂ (refs 1-3). In these two cases the structures of the melts seem to be very different to that found for the simpler diamond-like solids: they have a much lower coordination number, and the binary compounds CdAs₂ and CdP₂ seem to be the glass forming materials.

(8) There is an interesting parallel between the formation of mixed clusters and the behaviour of an eutectic mixture on cooling. At the eutectic temperature two phases crystallise simultaneously but, usually, on a scale which is orders of magnitude larger than has been discussed so far. If it were possible, however, for example by fast cooling, to induce a mixed cluster type structure, the result should be a glass. This may account for the formation of metallic glasses such as Pd₈₀Au₁₁Si₉ by splat cooling²⁵. Such materials tend to recrystallise near T_g as would be expected from this model.

(9) A particularly interesting possibility is that cluster-cluster interfaces (with their attendant strains and voids) at the surface may be associated with the generation of Griffith cracks, which limit the tensile strength of all glasses. Rindone²⁷ notes that "... microheterogeneities of different composition will have different chemical reactivities, especially with water. For example, a potassium-rich region would react with water much more rapidly than would a sodium-rich region. This could lower the strength considerably if there are local tensile stresses around the microheterogeneity due to thermal expansion differences ..."

The strained mixed-cluster model, therefore, offers explanations for a wide range of properties found in glasses and can also be used to predict interesting new possibilities. It is, however, only a descriptive approach and obviously requires detailed development before it could be used in anything but the crudest manner. It also may not be applicable to glasses formed from two- or one-dimensional crystal structures, such as long chain polymers, or, even, As₂S₃. This last material in fact seems to be known only in one crystal structure (even though there is a mention of a red β -As₂S₃ in the old literature²⁶) and so, formally, may be an exception to the rule proposed above.

I thank C. F. Drake and I. F. Scanlan of these laboratories, A. J. Apling of Warren Spring Laboratories, Stevenage, J. H. Konnert and J. Karle of Naval Research Laboratories, Washington DC, W. B. White of Pennsylvania State University, and P. Duwez of the California Institute of Technology for discussions.

Magnetic vibrational optical activity in the resonance Raman spectrum of ferrocytochrome c

L. D. Barron*

University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, UK

The first observations of magnetic Raman optical activity are reported. Using a field of about 0.7 T, Raman circular intensity differentials up to $\pm 4 \times 10^{-3}$ are induced in resonance Raman bands of ferrocytochrome c.

OPTICAL activity associated with molecular vibrations can now be studied through a difference in the intensity of Raman scattering in right and left circularly polarised incident light¹⁻⁴.

* Present address: Chemistry Department, The University, Glasgow G12 8QQ, UK.

Effects found so far in naturally optically active molecules indicate that the Raman circular intensity differential (CID) is a powerful probe of configuration and conformation. All molecules are rendered optically active by static magnetic fields, and should show Raman CIDs if the magnetic field is parallel to the incident laser beam⁶. Magnetic Raman optical activity has not been observed so far at transparent frequencies, but is reported here in the resonance Raman spectrum of ferrocyclochrome *c*, a haem protein, using a modest magnetic field.

There are many problems in the application of conventional vibrational spectroscopy to biological molecules. Infrared radiation is absorbed strongly by water, the ubiquitous biological material, and the complexity of biological molecules can lead to thousands of normal modes of vibration. Raman spectroscopy does not suffer from the first limitation as water does not absorb visible and near ultraviolet wavelengths and scatters them only weakly. The second limitation can be overcome through the resonance Raman technique in which the laser frequency falls within an electronic absorption band, usually localised at a site of biological function such as a haem group, resulting in a tremendous enhancement of the Raman intensities of those few vibrations coupled to the electronic transition⁶.

It would clearly be of interest if CIDs could be observed in the resonance Raman spectra of biological molecules as vibrational optical activity, both natural and magnetic, is expected to be sensitive to the delicate configurational and conformational features that determine biological function. Attempts to observe natural optical activity in the resonance Raman spectra of haem proteins and visual pigments on retinal membranes have not been successful so far, possibly because electron conjugation tends to minimise the chirality by holding the chromophores nearly planar. But as porphyrin rings are very susceptible to magnetic perturbations and show large magnetic, optical rotatory dispersion and magnetic circular dichroism^{7,8}, haem proteins are extremely suitable for the observation of magnetic resonance Raman optical activity. Furthermore, the resonance Raman phenomenon enables the contributions from those electronic transitions most susceptible to magnetic perturbations to be isolated, whereas in transparent regions all electronic transitions contribute to Raman scattering.

The quantity that is measured is a dimensionless CID in the light scattered at 90°:

$$\Delta_\alpha = (I_\alpha^R - I_\alpha^L) / (I_\alpha^R + I_\alpha^L) \quad (1)$$

where I_α^R and I_α^L are the scattered intensities with α -polarisation in, respectively right and left circularly polarised incident light. If z is the direction of the incident beam, I_z and I_x are linearly polarised parallel and perpendicular to the scattering plane, yz (Fig. 1). Δ_z and Δ_x are referred to, respectively, as the depolarised and polarised CIDs.

Magnetic Rayleigh and Raman optical activity originate in interference between the scattered electromagnetic waves whose

Fig. 1 The geometry for polarisation experiments in Raman scattering at 90°. z , Direction of the incident beam; y , direction of the detected beam; R , right circular polarisation; L , left circular polarisation.

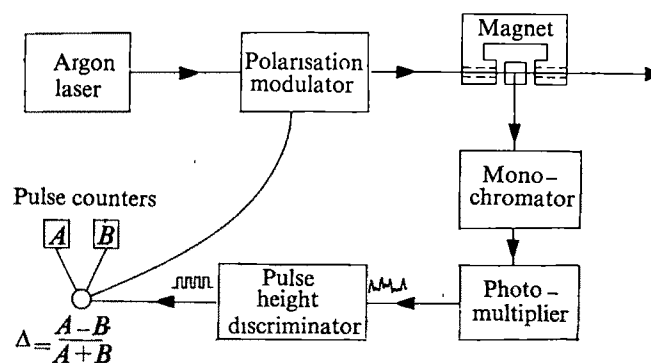

Fig. 2 The experimental arrangement for measuring magnetic Raman CID. A beam from an argon-ion laser is brought to a broad focus in the sample, which is held in a quartz fluorescence cell with a path length of 1 cm. The sample cell is situated between the poles of a permanent magnet with holes bored through the pole pieces so that the magnetic field is parallel to the laser beam. The light scattered at 90° is processed by a triple monochromator and the Raman components detected by a photomultiplier which produces measurable voltage pulses from individual photon strikes. These pass through a discriminator which gives equal weight to all pulses which exceed a certain voltage threshold; this enables much of the noise from the photomultiplier to be eliminated, and gives the scattered intensity as a 'photon' count rate. The polarisation of the incident beam is modulated directly between right and left circular at 9 Hz using a potassium-dihydrogen phosphate crystal driven by a square wave alternating voltage synchronised with two matched pulse counters. While the modulator performs the first half of its cycle and produces right circular polarisation, pulses are channelled into counter *A*; while the modulator performs the second half of its cycle and produces left circular polarisation, pulses are channelled into counter *B*. After accumulating a statistically significant number of counts, the sum of the two counters $A+B = I^R + I^L$ and the difference $A-B = I^R - I^L$ are read. The statistical significance of N counts is determined by the standard deviation \sqrt{N} . Thus, on 10^8 counts, the 'statistical noise' is $\sqrt{N}/N = 10^{-4}$, which is an order of magnitude smaller than the larger CIDs expected. Only the depolarised CIDs are sampled (see refs 2 and 4).

amplitudes are proportional to the usual electric dipole-electric dipole polarisability tensor and the same tensor perturbed to first order in the component of the magnetic field along the direction of the incident beam. The basic theory of magnetic Rayleigh and Raman CID was worked out by Barron and Buckingham⁶, although the final expressions apply only to Rayleigh and Raman scattering at transparent frequencies and to Rayleigh scattering at absorbing frequencies. That is because at transparent frequencies, to a good approximation, the real part of the transition polarisability is purely symmetric and the imaginary part is purely antisymmetric; but at resonance this approximation breaks down completely and, in general, the real transition polarisability contains an antisymmetric part and the imaginary transition polarisability contains a symmetric part.

The arrangement for measuring magnetic Raman CID is illustrated in Fig. 2.

One problem anticipated with resonance Raman CID measurements is a bias caused by the circular dichroism of the incident beam. But none was detected to within $\pm 1 \times 10^{-4}$, probably because the magnetic circular dichroism of ferrocyclochrome *c* at 5,145 Å is very small⁹. In general, this problem could be overcome by tuning the laser frequency to coincide with the one or more nodes that often occur within a magnetic circular dichroism band.

The depolarised magnetic resonance Raman CID spectrum of ferrocyclochrome *c* is shown in Fig. 3. There is good reflection symmetry on reversing the magnetic field direction, and no significant CIDs are found when the field is removed. Magnetic CIDs occur in most of the strong resonance-enhanced Raman bands between 1,100 and 1,600 cm^{-1} . No significant effects are found in the weaker bands in other parts of the spectrum.

These magnetic Raman CIDs involve vibrations of symmetry species B_1 , B_2 and A_2 , assuming an effective symmetry of C_{4v} .

Fig. 3 The depolarised magnetic circular intensity sum (a) and difference (b and c) spectra of ferrocytochrome c. The magnetic field directions are opposite in b and c. Experimental conditions: 1×10^{-4} M aqueous solution of cytochrome c with excess sodium dithionite; magnetic field strength about 0.7 T; laser wave-

length, 5,145 Å; laser power, 500 mW; slit width, 13 cm⁻¹. The $I_z^R - I_z^L$ spectra were recorded manually at fixed points with a counting period of about 8 min. To estimate the dimensionless CIDs, the background should first be subtracted from the $I_z^R + I_z^L$ spectrum.

for the porphyrin ring in ferrocytochrome c, and the symmetry assignments are indicated in the top spectrum. In brackets are shown the minor contributors that arise because the planar tetragonal symmetry of the basic porphyrin ring, which provides a useful first approximation to the classification of the spectroscopic properties, is actually distorted by thioether side groups which link the haem to the protein¹¹.

The resonance Raman scattering process involves transitions from the zero vibrational level of the porphyrin ground electronic state to higher vibrational levels of the first π^* excited electronic state (${}^1E_u \leftarrow {}^1A_{1g}$)¹². Since the ground electronic state is non-degenerate there is no ground state magnetic moment, so the observed magnetic Raman CIDs should be independent of temperature. And as the excited electronic state is doubly degenerate the parts of the magnetically-perturbed transition polarisability that correspond to generalised forms of the Faraday A term of magnetic circular dichroism¹³ should dominate.

A detailed analysis of the magnetic Raman CID spectrum would be premature since the theory is not sufficiently developed and the spectrum is poorly resolved. It is, however, worth noting that the largest magnetic CID ($|\Delta_z| \sim 4 \times 10^{-3}$) is found in the Raman band at about 1,132 cm⁻¹, which originates in a single vibrational mode of A_2 symmetry. Since the corresponding transition polarisability is completely antisymmetric, the band shows the striking phenomenon of inverse polarisation¹⁴, which has so far only been found in resonance Raman bands and is critically dependent on the laser wavelength¹⁵. The other A_2 modes show only weak or negligible magnetic CIDs, and when interpreted these relative CID intensities and their variation with laser wavelength may lead to a better understanding of the

molecular mechanism of antisymmetric resonance Raman scattering, which is still obscure.

The interpretation of the magnetic CID spectrum will be facilitated when examples are found in other molecules, particularly free porphyrins and haemoglobins, in which the chromophore symmetry is better defined so that there is less mixing of the vibrational modes. Unfortunately, it has not yet been possible to obtain results from free porphyrins or haemoglobins since they do not survive long enough in the intense laser beam to allow significant CID measurements to be taken. But with more elaborate sampling arrangements and a stronger magnetic field (an order of magnitude increase is available with superconducting magnets), magnetic Raman optical activity should be accessible in many other samples.

I thank the Ramsey Memorial Fellowships Trust for the award of a Fellowship and Professor A. D. Buckingham for helpful comments.

letters to nature

No indication of excess MeV gamma radiation from the Crab Nebula

DURING the past two years results from two different balloon experiments^{1,2} indicate that the γ -ray emission from the Crab Nebula between 1 and 10 MeV is considerably above the straight line interpolation from lower and higher photon energies. The excess above the power law has been claimed to be factor of 7 between 1 and 3 MeV and of a factor 30 between 3 and 10 MeV. The fact that both experiments yielded nearly identical results gives support to the reality of the excess component. The power in this excess is nearly as large as the total integrated synchrotron power of 2×10^{-7} erg cm⁻² s⁻¹ of the Crab Nebula. It has been speculated that this powerful, narrow-band component may be produced in the pulsar magnetosphere, possibly near the surface of the neutron star².

Results of a balloon flight with our double Compton telescope^{3,4} now set an upper limit to the soft γ -ray flux between 1.5 and 10 MeV from the Crab Nebula which is in severe contradiction to the flux values published previously^{1,2} and rules out the existence of an excess—at least of this magnitude.

The telescope consists of two large plastic scintillator blocks, 1.20 m vertically apart. Both detectors are surrounded by an anticoincidence shield. A γ ray is identified by a first Compton collision in the upper detector and a second in the lower detector—this sequence being confirmed by a time-of-flight measurement. Energy and direction of the γ rays are determined by pulse height measurements in both detectors. The telescope has an acceptance cone of 26° half width at half maximum (HWHM) between 1.5 and 2 MeV, 23° between 2 and 3 MeV, 18° between 3 and 5 MeV and 14° between 5 and 10 MeV. The energy resolution is 40% FWHM at 2.75 MeV. The effective geometrical area for vertical incidence is zero below

1 MeV, increases to 1.6 cm² at 1.5–2 MeV, has a maximum of 2.6 cm² at 3–5 MeV and drops to 2.2 cm² at 5–10 MeV.

The transit of the Crab Nebula was 162 min after the balloon was launched. Because of the large acceptance cone of the telescope the detection probability of γ rays from the Crab drops to half its maximum value ~ 100 min after the transition and is zero ~ 50 min later. In Fig. 1 the total 1.5–10-MeV counting rate is plotted as a function of time after launch. Only those events are taken into account, which satisfy the so called $\bar{p} < 30^\circ$ restriction³ and which fall into a certain time-of-flight interval. No statistically significant excess of the counting rate is present over the full observation period. This is also true, if the total energy range is subdivided into four smaller intervals. Although events have also been triggered with energies below 1.5 MeV, these have not been taken into account to avoid uncertainties in the detection efficiency, which are caused at these energies by its strong dependence on the accurate setting of the trigger levels.

For each 20-min interval in Fig. 1 an upper flux limit of the Crab Nebula at the 95% confidence level was determined according to

$$r_{2\sigma} = \int_{1.5}^{10} S(E_\gamma) A \varepsilon(E_\gamma, \theta) f_i \exp \left[-\frac{2.5 \text{ g cm}^{-2}}{\lambda(E_\gamma) \cos \theta} \right] dE_\gamma \quad (1)$$

where $r_{2\sigma}$ is the 1.5–10 MeV 2σ counting rate uncertainty in Fig. 1; A is the detector area; $\varepsilon(E_\gamma, \theta)$ is the energy and zenith angle dependent detection efficiency; f_i is the fraction of events, for which the time of flight requirement is fulfilled; $\lambda(E_\gamma)$ is the

Fig. 1 1.5–10-MeV counting rate of the double Compton telescope as a function of time after launch. Only those events are taken into account for which a certain time of flight requirement and the so-called $\bar{p} < 30^\circ$ restriction³ is fulfilled. The balloon was launched from Palestine, Texas on July 11, 1974 at 0905 LT. The balloon reached its float altitude of 2.5 g cm⁻² within 145 min. During the first 4.6 h at float the telescope axis was adjusted to the zenith. Within the next 58 min the axis was rotated from 0 to 360° zenith angle to measure the zenith angle distribution of atmospheric rays. During the last 28 min at float altitude the axis was again adjusted to the zenith. Results from this flight on the diffuse cosmic γ -ray component and on the angular distribution of atmospheric γ -rays have already been published^{5,6}.

Fig. 2 Energy spectrum of the Crab Nebula. Our upper limits at the 2σ confidence level were derived from the assumption of a power law spectrum between 1.5 and 10 MeV of the form $\sim E^0$ or $\sim E^{-1.3}$.

mean free path of γ rays in the atmosphere; θ is the time-dependent zenith angle of the Crab Nebula; and $S(E_\gamma)dE_\gamma$ is the differential photon number spectrum of the Crab Nebula. For the Crab spectrum a power law with two different exponents has been considered:

$$S(E_\gamma)dE_\gamma = a_1 E_\gamma^{-\alpha_1} dE_\gamma \quad \text{photons cm}^{-2} \text{ s}^{-1} \text{ MeV}^{-1} \quad (2)$$

with $\alpha_1 = 1$ and $\alpha_2 = 2.3$. The first case describes the spectral form as determined by Baker *et al.* and Gruber, the second one is identical with the interpolation from lower and higher photon energies. For each 20-min interval the value for the proportional factor a_1 or a_2 was then determined applying equation (1). The most significant upper limit for the flux of the Crab Nebula is obtained if the limits of each interval from observation periods between 20 min before and 80 min after the transit are averaged quadratically. Then $a_1 = 2.41 \times 10^{-3}$ and $a_2 = 8.24 \times 10^{-3}$. These limits are shown in Fig. 2, where the energy spectrum of the Crab Nebula is shown from X-ray energies to be about 100 MeV.

The upper limit determined from our flight is at least a factor of 5 below the flux values quoted by Baker *et al.*¹ and Gruber² and is only a factor of 3 above the straight line interpolation from lower and higher energies.

If the flux values as determined by Baker *et al.* and Gruber were correct, the total counting rate of our telescope would have been a factor of 3 higher during the transit compared with the counting rate in the second half of our flight. In comparison, the flux value of Gruber was determined from only a 5% increase of the total counting rate; the increase shown by Baker

et al. was even less than 1%. Variations of this order are easily obtained by temperature shifts, electronic instabilities or geomagnetic effects. During our flight at float the temperature inside the gondola did not change by more than 3.5 K. Even if as a consequence the gain had shifted by 20%, which is a very extreme assumption, the counting rate shown in Fig. 1 would have changed at most by 40%, which is just as large as the 2.5σ uncertainty. The geomagnetic latitude continuously decreased from 42°N to 39°N during the flight. Therefore, the flux of the Crab Nebula can at most be overestimated, but cannot be underestimated. We conclude, therefore, that the excess of γ radiation from the Crab Nebula as reported previously^{1,2} does not exist. From our upper limit one could expect that the flux accepts the value of the straight line interpolation.

We thank Professor Pinkau for his interest and support, the personnel of NCAR for assistance with the balloon flight, and H. Arbinger, G. Pickl and F. Schrey for their assistance. C. M. was supported by a fellowship from the Deutscher Akademischer Austauschdienst.

Ultraviolet photoabsorption by halocarbons 11 and 12 from electron impact measurements

DEPLETION of the stratospheric ozone layer by chlorine atoms released through solar photolysis of the chlorofluoromethanes is a matter of widespread concern¹. Predictions of the magnitude and time development of this effect depend on large scale models of atmospheric transport and photochemical kinetics which require reliable data on the primary reaction processes involved. One important input is the ultraviolet absorption spectrum of halocarbons 11 and 12, that is, CFCl_3 and CF_2Cl_2 , respectively. Published optical determinations² of the absorption spectra for these molecules between 200 and 120 nm (that is, 6.2 and 10.33 eV) have been called into question, however, by the measurements of Rowland and Molina³.

We have obtained oscillator strength distributions for a number of molecules^{4,5} from high quality electron energy-loss spectra. Previous studies have shown excellent agreement (better than $\pm 15\%$) between electron impact and optical values below 15 eV, that is, for wavelengths longer than 80 nm.

Electron energy-loss spectra for CFCl_3 and CF_2Cl_2 were obtained digitally with the NBS model AN-1 electron impact spectrometer⁵ for 100 eV electrons scattered within 20 mrad of the incident direction. Halocarbon gases were obtained commercially and used without further purification. Subsequent analysis by gas chromatography confirmed a purity greater than 99.8% with the only identifiable impurity being 0.1% CF_2ClH in CF_2Cl_2 .

Relative oscillator strength distributions for CFCl_3 and CF_2Cl_2 were derived by a procedure⁶ that corrects for the finite

angular acceptance of the apparatus. For CF_2Cl_2 (halocarbon 12) the relative distribution was then normalised at an energy loss of 12.22 eV to a value $dI/dE = 0.732 \text{ eV}^{-1}$ obtained from an unpublished photoabsorption cross section of $80.3 \pm 2.4 \times 10^{-18} \text{ cm}^2$ measured by J. C. Person and coworkers at 101.4 nm. Their absolute accuracy of $\pm 3\%$ is much better than that quoted by Gilbert *et al.*⁶. Our values are within $\pm 5\%$ of the measurements of Person *et al.* between 12 and 15 eV but are nearly a factor of 1.4 higher than those of Gilbert *et al.*⁶ in this region. Between 10.4 and 11.4 eV, however, our values agree well with those of Gilbert *et al.*⁶. In fact, our disagreement with their optical data occurs mainly in the spectral region where they used a windowless absorption cell. This leads us to suspect some undetermined error in their measurements associated with the absence of windows.

For CFCl_3 (halocarbon 11) only the data of Gilbert *et al.*⁶ are available for normalisation. Since we obtain good agreement with their values between 10.4 and 11.4 eV for halocarbon 12, we have normalised our halocarbon 11 data at 10.76 eV to $dI/dE = 0.906 \text{ eV}^{-1}$. This value corresponds to their molar extinction coefficient⁶ of $26,000 \text{ l mol}^{-1} \text{ cm}^{-1}$ measured at 115.2 nm. With this normalisation we found agreement with their values below 11.4 eV, but again in the windowless region our values are nearly twice as large. A more detailed analysis of the vacuum ultraviolet region for a large set of halocarbons is in preparation.

Our energy absorption results relevant to the ozone depletion problem are shown in Figs 1 and 2. A portion of our electron-impact data are compared with the optical measurements of

Fig. 1a, Comparison of oscillator strengths for halocarbon 11 (CFCl_3) in the ultraviolet absorption region: —, present electron impact results; \times , optical values from ref. 2; Δ , optical values from ref. 2 as quoted in ref. 3; \bullet , optical values from ref. 3. b, Comparison of oscillator strengths for halocarbon 12 (CF_2Cl_2) in the ultraviolet absorption region (identifications as in a).

Table 1 Apparent photoabsorption cross sections for CFCl_3 and CF_2Cl_2 derived from electron energy-loss measurements

λ (nm)	Apparent photoabsorption cross section* (cm^2) CFCl_3	CF_2Cl_2
225	1.11 (−20)	—
221	2.20 (−20)	—
218	4.55 (−20)	1.97 (−21)
214	9.77 (−20)	4.50 (−21)
210	1.64 (−19)	1.08 (−20)
207	2.90 (−19)	2.63 (−20)
203	4.77 (−19)	5.16 (−20)
200	6.82 (−19)	1.02 (−19)

163	5.88 (−18)	5.98 (−19)
159	5.15 (−18)	6.87 (−19)
155	3.89 (−18)	9.46 (−19)
151	4.76 (−18)	1.07 (−18)
148	7.74 (−18)	9.45 (−19)

*The number in parentheses is the exponent of the power of ten to be multiplied by the value of the cross section tabulated

Doucet *et al.*² and the work of Rowland and Molina³. The oscillator-strength distributions we obtain for halocarbons 11 and 12 include energy absorption in the so-called "window" region of the solar radiation flux³. These data extend from the Hartley band of O_3 (maximum at 4.9 eV or 255 nm) to the Schumann–Runge continuum of O_2 (maximum at 8.5 eV or 146 nm). Our data confirm the measurements of Rowland and Molina³ for both halocarbons and disagree by as much as a factor of two for halocarbon 11 and a factor of four for halocarbon 12 with earlier measurements². Further, our results differ from those of Doucet *et al.*² over a significant portion of the absorption spectrum at higher energies for both halocarbons.

One can calculate apparent photoabsorption cross sections from the present results (Fig. 1) by multiplying by a conversion factor of $1.0975 \times 10^{-16} \text{ cm}^2 \text{ eV}$. Justification of our procedure for obtaining apparent photoabsorption cross sections from electron impact data depends on the theory of limiting oscillator strengths⁷ and is subject to the same qualifications we have discussed previously⁶. Since these data are relevant to atmospheric model calculations assessing the impact of continued halocarbon releases, the apparent photoabsorption cross sections obtained from our measurements are given in Table 1.

We thank Dr J. C. Person, D. Fowler, and P. P. Nicole (Argonne National Laboratory) for providing their photoabsorption cross sections for halocarbon 12 before publication, and Dr P. Ausloos (National Bureau of Standards) for analysing our gas samples. This work was supported in part by the US Energy Research and Development Administration.

Aromatic units in coal

THE organic matter in coal consists largely of a macromolecular material of complex and variable composition. When coal is pyrolysed, a large fraction is converted to char, and a number of complex aromatic compounds are formed. Because of the

extensive chemical change which takes place during this process, however, it is not clear what relationship the products have to the original structure of coal. Many workers have used oxidation procedures to degrade coal to simpler species which are more readily interpreted in terms of coal structure. Oxidation products, however, were in general studied by limited classical organic chemistry methods for separation and identification of products^{1,2}. To date the only aromatic acids definitely identified have been the carboxylic acids of benzene^{3,4}. Commonly used oxidants have been HNO_3 , $\text{HNO}_3\text{-K}_2\text{Cr}_2\text{O}_7$, KMnO_4 , O_2 and $\text{H}_2\text{O}_2\text{-O}_3$ in conditions for drastic degradation of aromatic rings. On the basis of results of oxidation of coal with a selective oxidant, NaOCl , Chakrabarty and Berkowitz have suggested⁵ that coal has a largely non-aromatic "tricycloalkane or polyamantane" structure. They pointed out that no evidence for aromatic compounds other than benzene derivatives was found in their oxidation product. Our experimental data do not support

*Benzene tricarboxylic acid methyl ester is normalised to 100.

†Methoxy compounds may result from the reaction of phenolic compounds with diazomethane. Methoxyphenanthrene may be derived from the reaction of fluorenone with diazomethane¹⁴.

‡Although the phenanthrene ring is not affected during oxidation, anthracene is oxidised to anthraquinone⁶.

§Methyl esters of pyrene carboxylic acids show very similar mass spectra, however, the pyrene ring is extensively degraded by present procedure⁸.

¶These compounds might be oxidised further to benzene-carboxylic acids in our experimental conditions.

||It is probable that our estimates of the first two dibenzofurans are somewhat high because of contribution from fragments of xanthenes which lose both CO and OCH_3 to give the corresponding dibenzofuran ions.

Illinois bituminous coal was finely powdered, heated with 12 N HCl and washed. The same procedure was repeated three times, and the coal dried at 120 °C. The sample contained 71.33% carbon.

Table 2 N-heterocyclics found in the photochemical oxidation of coal in alkali solution, identified as methyl esters of carboxylic acids

Nucleus	Number of -COOCH ₃	Elemental composition	Precise mass (M-OCH ₃) ⁺		Relative* abundance (±15–20%)
			Observed	Deviation × 10 ³	
Pyridine	3	C ₁₀ H ₈ O ₅ N	222.0408	0.5	3.0
	4	C ₁₂ H ₁₀ O ₇ N	280.0488	3.2	3.5

	3	C ₁₇ H ₁₂ O ₇ N	310.0708	−0.6	5

*Benzene tricarboxylic acid, which is the most abundant aromatic acid in this oxidation product, is normalised to 100.

†Carbazole is sensitive to oxidation with oxidising agents; however, this nucleus is stable during photochemical oxidation as shown by our own experiments with authentic carbazole and N-ethyl carbazole.

Demineralised fine powdered coal was suspended in either 10% HCl or 5% KOH aqueous solution, and oxidised with air by the radiation of a high pressure mercury lamp for 7–10 d at 40–50 °C.

this view but rather the generally accepted idea that coal is predominantly an aromatic material.

We have identified 35 aromatic carboxylic acids resulting from the oxidation of bituminous coal with aqueous Na₂Cr₂O₇ (Table 1). This oxidation procedure was chosen as it had been shown⁶ that it will oxidise substituted polycyclic aromatic compounds in good yields to their corresponding polynuclear carboxylic acids with a minimum of ring degradation. It seemed probable, therefore, that aliphatic and alicyclic linkages between aromatic units in coal would be broken, with the formation of carboxylic groups and the release of smaller aromatic units.

Illinois bituminous coal (3.6 g Peabody coal from seam No. 2) was heated at 250 °C in 120 ml 0.4 M Na₂Cr₂O₇ in a stainless steel autoclave for 36 h. The aromatic acids formed were isolated by a method similar to that of Friedman *et al.*⁶. The coal, which was almost completely insoluble in either

aqueous or organic solvents, was completely solubilised with the resulting acids weighing 53% of the original weight of coal. The acids were converted to methyl esters with diazomethane to increase their volatility for subsequent mass analysis. Individual compounds were identified by a time of flight mass spectrometer with a temperature-programmed solid inlet⁷, and verified by a precise mass determination with a high resolution mass spectrometer-computer combination. The mass spectra of methyl esters of aromatic carboxylic acids are relatively simple. The most abundant peak in practically all cases is formed by the loss of a methoxy group from the molecular ion (M-31)⁺ (refs 8–10). In addition, sizeable molecular ions and (M-COOCH₃)⁺ are observed and were used to verify the identification of each compound. Relative abundances were estimated from an integration of the base peak of each compound during the time that a sample was completely volatilised in the mass spectrometer.

**Fig. 1** Aromatic units indigenous to coal.

Table 1 summarises the data for the methyl esters of the 35 aromatic acids which were positively identified. Another 16 oxygen-containing ions in considerable yield were observed in the mass spectra of the acid fraction but not identified.

In addition several series of interesting aromatic derivatives were observed in the chemically neutral fraction. These included dibenzo-*p*-dioxins, benzoxanthones, benzantraquinones and acridones. These compounds exhibit an abundant M^+ as the base peak of the spectra¹¹. Amphoteric nitrogen-containing acids have not been isolated from the dichromate oxidation product because of some experimental difficulties. Seven nitrogen-containing aromatic acids produced in a photochemical oxidation were, however, identified (Table 2). Figure 1 shows the structural formulae of the aromatic units we believe to have been indigenous to the coal. Fluorenone and anthraquinone may have been produced by oxidation of fluorenes and anthracenes, respectively.

Of particular interest are the heterocyclic units of Fig. 1 with O, S, and N in ring systems. Little is known about the chemical state in coal of these important elements^{12,13} which are particularly troublesome in processes for conversion of coals to liquids and gases. Some of the aromatic units (Fig. 1) have been observed in tars produced by pyrolysis or other high temperature processes but it was not known whether these were indigenous or were produced in the process. For example benzo- and dibenzothiophene are formed when sulphur is heated with a variety of hydrocarbons. It is not likely that such compounds were formed in our low temperature aqueous oxidation experiments and thus thiophene derivatives must be indigenous to coal.

The complexity of the observed aromatic acids—with up to five carboxylic groups on benzene and up to four on polycyclic aromatics—suggests a high degree of aliphatic or alicyclic linkages between aromatic units. Such linkages are more readily oxidised than are the aromatic rings.

We thank Mr Melvin McKee of Peabody Coal for coal samples.

First fossil records of cephalopod statoliths

THE class Cephalopoda is represented by over 10,000 fossil species and about 1,000 living species. Almost the entire fossil record so far described consists of external or internal calcareous shells of the Ammonoidea, the Nautiloidea and

some members of the Coleoidea. The subclass Coleoidea includes all but three (*Nautilus* spp.) of the living species of cephalopods, and is represented in the fossil record largely by the order Belemnitida which is important from the early Jurassic to the Eocene. Another coleoid order, the Sepioidea, including the living *Sepia* and *Spirula* have internal calcareous shells, and have left traces from the Upper Jurassic (*Voltzia*) to the present. The three remaining coleoid orders, the Teuthoidea, the Vampyromorpha and the Octopodida include all the remaining living cephalopods, comprising 29 teuthoid or squid families, one vampyromorph family and 12 octopod families.

With the exception of *Argonauta*, the 42 extant cephalopod families have no calcareous shells and such fossils as are known consist of body imprints, beaks, hooks, radulas, chitinous pens and ink sacs. Of these, beaks¹, body imprints and pens² have the most potential in relating fossils to living forms but are too few at present to allow the construction of even the most modest of phylogenetic trees.

Fig. 1 *a*, The posterior and, *c*, anterior surfaces of, respectively, right and left statoliths from a Miocene deposit (Olcese Sand, California); *b*, the posterior and, *d*, anterior surfaces of respectively, right and left statoliths of a living oceanic squid, *Todarodes sagittatus*. Scale, 1 mm.

There are, however, other hard structures in cephalopods, which have so far been neglected in the study of both living and fossil forms. These are known as statoliths (= otoliths of some authors), small, paired calcareous stones with a complicated shape very characteristic of the Sepioidea and Teuthoidea, although the basic pattern varies within those groups.

Statoliths of at least one species of cephalopod are composed of aragonite, a stable form of calcium carbonate commonly found in fossils, including the fossilised otoliths of fish. It is, therefore, not surprising that cephalopod statoliths should be discovered in Cainozoic deposits. It is, however, of particular interest as it offers a possibly definitive technique for unravelling Cainozoic cephalopod phylogeny. Figure 1*a-d* compares anterior and posterior views of left and right statoliths from a Miocene teuthoid with those from an individual of the extant *Todarodes sagittatus*. Though the latter (Fig. 1*b* and *d*) are white and slightly translucent, the fossils (Fig. 1*a* and *c*) are light brown and more opaque. They will be described in more detail elsewhere.

An examination of unidentified fossil otoliths and statoliths has revealed a number of squid statoliths from North American strata. To date they have been found in the Pleistocene of California (Timms Point Silt), the Pliocene of California (Lomita Marl and Pico Formation), the Miocene of California (Olcese Sand), Florida (Chipola Formation), Jamaica (Bowden Formation), and Virginia (Yorktown Formation), and the Oligocene of Mississippi (Glendon Limestone). In one Pliocene deposit (Lomita Marl), 185 of 24,299 otoliths and statoliths recovered from approximately one ton of fossiliferous matrix represented at least three kinds of squid species. Rare fossils, very similar to modern ommastrephids *Plesioteuthis*, are known from the Upper Jurassic, suggesting that statoliths are likely to be found in strata older than the Cainozoic.

Statocysts of living cephalopods have been described by several authors³⁻⁷ but no detailed description or comparative study of the hard calcareous statolith (= otolith) has so far been published.

M. R. Clarke (unpublished) found that the statoliths of *Ommastrephes* were composed of aragonite, and in another study attempted to relate growth to the rings seen in the statoliths of *Todarodes sagittatus*. Unaltered aragonite fossils (teleost fish otoliths, mollusc shells, and so on) are abundant throughout the Cainozoic, and sometimes afford the only method of identifying faunal components^{8,9}. Indeed, fish otoliths have proved very useful in tracing the history of Recent genera, and there seems every possibility that statoliths will help clarify the relationships of Recent families, and possibly even genera, of the Cephalopoda. A study of the variation of statoliths in Recent families of cephalopods is now in progress, and it is already evident that within the limits of the general pattern the form varies considerably between and within families.

Fossil cephalopod statoliths should provide not only a means of studying phylogeny but, in addition, the relative numbers of statoliths of different families should provide an indication of the relative importance of the various families living at a particular locality and time.

fluctuation field¹. A two-dimensional array study operated over a wide area of southern Australia has detected anomalous effects at the eastern edge of the seismically active Flinders Ranges². Various interpretations have been suggested for the Flinders anomaly³ and interpretations of the accompanying seismicity³ have been given in terms of plate tectonics⁴. Independent seismic evidence⁵ indicates that there is no abrupt step in crustal and upper mantle structure from west to east across the Flinders Ranges, though there may be a gradual change. A magnetometer array in south-eastern Australia has detected anomalous effects in southern Victoria⁶, and the interpretation of a subsequent study has located the anomaly more exactly (F. E. M. L., unpublished), placing the conductor causing it under or near the Otway Ranges, another region of Australian continental seismicity. Consequently, all the major continental conductivity anomalies so far discovered in Australia are in regions of earthquake activity (Fig. 1).

The earthquakes plotted in Fig. 1 occurred between 1897 and 1972, and the distribution of observatories on the continent over this time has probably influenced the seismicity pattern shown. Several major earthquake zones are apparent, though on a world scale the seismicity of the Australian continent is low.

It is possible that the electrical conductivity anomalies and seismic zones are geographically related. Shallow conductivity anomalies could arise because fracturing has broken up the surface rocks, allowing continuity in saline ground waters to provide a conducting channel. This mechanism is, however, not entirely satisfactory for the Otway Anomaly, which may extend deeper than the seismic zone.

Beneath fracture zones, motion along fault planes presumably occurs by some type of ductile flow. Such ductile shearing of rock may increase greatly its electrical conductivity and produce a deep electrical conductivity anomaly, either by causing a change in rock fabric⁷ (for example the presence of a graphite schist has been postulated to explain a major conductive structure in North America⁸), or simply by heating. The rheological process of ductile flow beneath continental earthquake zones may involve the conversion of considerable quantities of mechanical energy to heat.

Magnetic fluctuations may in future be observed over the more northern centres of Australian seismicity (see Fig. 1) which have not yet been covered by magnetometer array studies. Because of present interest in the thermal balance of active faults⁹, heat flow data are being collated, although heat flow values would not necessarily be expected to be high: increased conductivity could result from quite a minimal increase in temperature at depth were that temperature already near the melting point, thus forming a partial melt.

If a general relationship between seismic activity and electrical conductivity anomalies is established there may be several implications for projects of earthquake prediction. The first is that deep electrical conductivity may vary both before and after an earthquake, as a consequence of associated variations in the ductile flow. (I do not mean to imply that such variations would be detected by a magnetometer array; perhaps controlled-source, electrical methods would be most suitable.) The second implication is that any observations of magnetostrictive changes in the Earth's static magnetic field may need to be corrected for non-uniform magnetic fluctuations arising from local conductivity anomalies. Such corrections may be possible if magnetostrictive observations are taken on an array basis, and full geomagnetic induction tensors¹⁰ are estimated for each observing site.

I thank J. R. Cleary, D. Denham, T. J. Fitch and L. Thomas for discussion on seismicity, and M. J. S. Johnson and P. M. Davis for discussion on earthquake prediction.

Electrical conductivity anomalies and continental seismicity in Australia

Tyndall figures at grain boundaries of pure ice

LIQUID figures produced by internal melting in ice are called Tyndall figures (see refs 1-3). I report here the

formation and morphology of Tyndall figures at grain boundaries in pure ice.

I produced Tyndall figures at grain boundaries by focusing radiation from a small lamp into an area of $2 \times 2 \text{ mm}^2$ in an ice specimen which had grown from degassed, distilled and deionised water in stainless steel containers, and which had reached melting point as indicated by veins of water forming along the intersections of three grain boundaries⁴.

Two Tyndall figures with a vapour cavity were formed at a grain boundary (Fig. 1a). The vapour cavities—the black parts in Fig. 1a—are produced because of the density difference between ice and water¹. The Tyndall figures are inclined to the plane of the figure. The dashed arrows and the solid arrow (Fig. 1a) show the veins of water and the intersection of the melt grain boundary and the specimen surface, respectively. The surface of the melt boundary is not flat.

Fig. 1a shows that small perturbations are formed at the periphery of the Tyndall figures. Such perturbations were observed at the periphery of disk-shaped Tyndall figures formed in the basal plane. When the figures in the basal plane developed to a certain size, they became truncated cones and the perturbations began to be nucleated at the edge where the side face and the planar plane of the figures intersected³. On the other hand, the perturbation of

Fig. 1 *a*, Tyndall figures in a grain boundary; *b*, a 12-branched Tyndall figure; *c*, shape of a large branch of a Tyndall figure.

Tyndall figures at grain boundaries were observed even at an initial stage of their growth. Considering that the periphery of the figures at grain boundaries is always sharp because the angle where the figures meet the boundaries is 32° in the liquid phase (see ref. 4), I conclude that this kind of perturbation is nucleated at sharp edges.

During the growth of the Tyndall figures at the grain boundaries their shape changed, though some perturbations disappeared and others were nucleated. When the growth rate was large, the perturbations were sharp and their number increased. On the other hand, when the growth

rate was small, the perturbations were wide and their number decreased. The minimum number of perturbations that I observed was 12 (Fig. 1*b*).

Twelve-branched snow crystals, though rarely observed in nature, have been reported by some authors. Nakaya⁶ has examined them and concluded that they comprise two hexagonal crystals, one attached to the other. Kobayashi and Furukawa⁷ have explained their formation in terms of rotation twinning. This mechanism cannot be applied, however, to their formation because, although the orientation of adjoining grains in Fig. 1*b* could not be measured, it is clear from other observations that the morphology of Tyndall figures at grain boundaries does not depend on the orientation of the adjoining grains. Therefore, it is necessary to consider a new mechanism for the formation of 12-branched Tyndall figures.

When Tyndall figures grow large and the radiation on them becomes inhomogeneous, one of the perturbations grows preferentially and a large branch forms (Fig. 1*c*). The direction of the branch changes slightly but is usually straight. The configuration of the twigs on the branch shown in Fig. 1*c* is different from that of Tyndall figures formed in the basal plane. The angle between twigs and branches of Tyndall figures formed in the basal plane is 60° ; on the other hand, the angle between Tyndall figures at grain boundaries is 60° , 75° and 90° . The configuration of twigs on Tyndall figures at grain boundaries is similar to that observed on Tyndall figures formed in the crystallographic plane perpendicular to the basal plane (see ref. 2). This similarity may occur because the non-basal plane is less closely-packed than the basal plane.

Photoelectrolysis of water using semiconducting TiO_2 crystals

FUJISHIMA and Honda¹ have indicated that TiO_2 can be used in a photoelectrochemical cell to decompose water with band-gap light ($h\nu \geq 3.0 \text{ eV}$). This process, termed photoelectrolysis, could have important implications for solar energy conversion and the 'hydrogen economy' if use can be made of visible light.

To understand some of the basic aspects of photoelectrolysis, we have studied the phenomena with rutile single crystals as a function of light intensity, internal cell potential and resistance, pH, and cathode material. Rutile crystal wafers (*c* axis in the wafer plane) were reduced in H_2 to produce an n-type conductivity of $0.3 \Omega^{-1} \text{ cm}^{-1}$, and were then polished, etched, and fabricated into electrodes.

TiO_2 electrodes were studied in two types of cell in which the cathodes were usually platinised platinum foil (2.2 cm^2). The first type was a homogeneous cell in which the TiO_2 and Pt electrodes were immersed in the same electrolyte. The second cell consisted of two separate compartments connected by a KCl-agar salt bridge so that the electrodes could be immersed in different electrolytes. The TiO_2 crystal was illuminated with broad band ($3,000\text{--}4,000 \text{ \AA}$) near-ultraviolet light with an intensity of

26 mW cm⁻². This irradiation was varied over four orders of magnitude with neutral density filters having absorbance (*A*) values of 1, 2 and 3.

The current-voltage characteristics of a TiO₂ crystal (area 0.76 cm², thickness 0.52 mm) were measured as a function of light intensity in the homogeneous cell using 1 N phosphate buffer (pH = 6.5). With cathodic (forward) bias, the *i*-*V* curves showed typical diode behaviour. In the third quadrant (cathodic bias and current) the results were independent of light intensity; in the second quadrant (cathodic bias and anodic current) the results depended on light intensity in the usual manner.

The *i*-*V* data for anodic (reverse) bias is shown in Fig. 1. In the dark and at low illumination levels (*A* = 3 and 2), the

Fig. 1 Current-voltage characteristics for a TiO₂ crystal electrode in 1 N phosphate buffer (0.33 M Na₂HPO₄ + NaH₂PO₄) as a function of light intensity (homogeneous cell). The dark current is essentially zero (< 10⁻⁴ mA) with anodic bias; *A* = 0 corresponds to 26 mW cm⁻².

curves again show normal diode behaviour. The current is determined by the availability of holes in the TiO₂, and this is proportional to light intensity. At higher intensities, however, two important changes occur: (1) when the bias is between zero (short circuit) and +0.3 V the photocurrent saturates at light intensities ≥ 0.26 mW cm⁻² (*A* = 2), and (2) above a critical bias of $\sim +0.3$ –0.4 V the photocurrent at *A* = 0 and 1 undergoes a sharp increase with bias accompanied by visible H₂ and O₂ evolution at the cathode and anode, respectively. At about +1.0 V, the photocurrent again saturates with respect to bias, but is now approximately proportional to light intensity.

The electrode potentials (against a standard calomel electrode (SCE)) for both TiO₂ and Pt are plotted in Fig. 2. As expected, the Pt potential is independent of light intensity, and above the critical bias exhibits the normal value for H₂ evolution.

Fig. 2 TiO₂ and Pt electrode potentials as a function of light intensity in the homogeneous cell (1 N phosphate buffer). The normal H₂ and O₂ evolution potentials are indicated. ---, $V_{Pt} - V_{SCE}$; —, $V_{TiO_2} - V_{SCE}$.

The TiO₂ electrode potential depends on light intensity. At 26 mW cm⁻², the O₂ evolution potential is -0.26 V; the normal value is +0.62 V. Lower illumination intensities produce smaller negative shifts of the O₂ potential. For H₂ evolution to occur with zero bias, the potential for O₂ evolution on TiO₂ must be shifted to the negative side of the H₂ potential (a shift of -1.23 eV in a homogeneous cell).

The necessity for anodic bias to produce gaseous evolution can be understood by considering an energy balance for the absorbed photon². For band-gap photons ($h\nu \geq E_g$):

$$E_g + E_b = V_B + (\Delta G/2F) + V_H + iR + (E_c - E_f) + \eta_{Pt} + \eta_{TiO_2} \quad (1)$$

where E_g is the band gap (3.0 eV), E_b the bias, V_B the potential barrier of the TiO₂-electrolyte junction (~ 0.8 eV), $\Delta G/2F$ is the free energy per electron for H₂O decomposition (1.23 eV), V_H is the drop across the Helmholtz layer in the electrolyte (~ 0.05 eV), iR is the ohmic loss (~ 0.05 eV), $(E_c - E_f)$ is the energy difference between the conduction band and the Fermi level in TiO₂ (~ 0.2 eV), and η_{Pt} and η_{TiO_2} are the respective electrode overpotentials (~ 0.1 eV for Pt). The estimate for the potential barrier (V_B) was determined from a Schottky-Mott plot of $1/C^2$ against E_b , where C is the capacitance of the depletion layer^{3,4}. Values indicated for the other terms in equation (1) are either well known or were calculated from basic considerations.

In equation (1), the input energy requirements for gaseous evolution are 3.3–3.5 eV. All the terms on the right, except for η_{TiO_2} , account for ~ 2.4 eV. Thus, the O₂ overvoltage, η_{TiO_2} , is estimated to be ~ 0.9 –1.1 eV. This results from kinetic limitations on the rate of hole injection from the TiO₂ space charge layer into the electrolyte.

Table 1 Power balance for photoelectrolysis

Cell*	Electrolyte	Internal cell resistance (Ω)	Bias (V)	Bias power (mW)	H ₂ evolution† (output chemical power) (mW)	Optical conversion efficiency‡ (%)
Homogeneous	1 N phosphate buffer	380	1.0	0.99	1.47	2.4

			+0.4	0.74	2.73	10.1

* Optical near-ultraviolet power input is 19.7 mW (3,000–4,000 Å).

† Output chemical power is based on heat of combustion of H₂ to H₂O(l), and equals $(3.543) \times r$ where $r = \text{cm}^3 \text{H}_2 \text{h}^{-1}$.

‡ Defined as (chemical power out – electrical power in)/(optical power in).

§ Electrical power withdrawn from cell.

¶ Efficiencies for the differential pH cell do not take into account the energy required to maintain the differential pH during photoelectrolysis.

One intriguing way of supplying the anodic bias is to create a protonic concentration gradient between the Pt and TiO₂ electrodes. This was done in the differential cell by placing the TiO₂ electrode in 0.1 N KOH and the Pt electrode in 0.2 N H₂SO₄. The i - V characteristic of this cell is shown in Fig. 3; at zero bias, vigorous evolution of H₂ and O₂ occurs. Gaseous evolution can be maintained even with a cathodic bias, meaning that both chemical and electrical power can be withdrawn from the cell.

Fig. 3 The i - V characteristic and electrode potentials for TiO₂ and Pt in a differential pH cell (0.1 N KOH/0.2 N H₂SO₄). The normal H₂ and O₂ evolution potentials are indicated for each compartment.

Although the rest potential of the cell is 0.78 V, no current flows in the dark under short circuit or anodic bias conditions. The electrode potentials are also shown in Fig. 3. The Pt electrode shows the normal H₂ evolution potential at all current densities. The potential for O₂ evolution on illuminated TiO₂ is shifted by ~ -1.0 V.

A power balance was made for both types of cell by measuring the input electrical and optical power, and the output chemical power (that is, the H₂ evolution rate). The results are summarised in Table 1. They show that (1) the optical conversion efficiency (OCE) is maximised at $\sim +0.8$ V for the homogeneous cell (3–4%) and at $+0.2$ V for the differential cell ($\sim 11\%$); (2) the OCE increases with decreased internal cell resistance but is unaffected by pH; and (3) the H₂ evolution rate is very sensitive to bias between $+0.4$ and 1.0 V. Additional studies of cell parameters show that the OCE increases with decreased light intensity, and that the critical bias using other metal cathodes is increased by the difference between their H₂ overvoltage and that of platinised Pt.

In summary, these studies show that the necessity of a bias for H₂ evolution arises from an O₂ overvoltage of about 1 V at the TiO₂ anode; the bias can be applied either with an external voltage or by creating a concentration gradient within the cell. The viability of photoelectrolysis with anodic bias must be examined further, especially for the cases where smaller band gap semiconductors are contemplated for improved solar absorptivity.

I note that other workers⁵ have also measured optical conversion efficiencies for TiO₂ which are comparable with the values reported here.

I thank J. J. Gilman, G. G. Libowitz, D. Pouli and F. E. Williams for discussions, and W. W. Anderson and A. Linz for preprints.

Technique for the study of diffusion of large molecules in polymers based on infrared microdensitometry

THE diffusion of small molecules (in the gaseous, vapour or liquid phases) through polymeric matrices has been the subject of much study¹, and the techniques for such studies are, by and large, well established. Similar studies in the case of large molecules (broadly speaking, those forming solids at room temperature) in polymers, including polymeric self-diffusion, have been more rare²⁻⁵. Existing techniques for measurements of the diffusion of large molecules in synthetic polymers rely mainly on radioactive labelling of the diffusants. Nuclear magnetic resonance (NMR) has been used⁵, but is limited to measurements of diffusion in the melt, and also to relatively high diffusion rates⁵. Measurements involving radioactively labelled diffusants have two major shortcomings, in addition to the necessity of having to obtain the required labelled material: they fail with diffusants which are surface active with respect to the polymer², and they may involve significant interfacial resistance which the method does not reveal^{1,3}.

We have developed a simple technique for the measurement of the translational diffusion of large molecules in polymeric matrices, based on microdensitometry in the infrared. Essentially, a step function in the concentration of the diffusant is set up within the bulk matrix, and diffusion is allowed to occur at the required pressure and temperature. At some known time the diffusion is effectively terminated by quenching, and a thin slice through the composite centre is removed and scanned in the microdensitometer (Fig. 1).

To obtain a measure of the concentration of the diffusant it is necessary that it absorb at some infrared frequency unaffected by the bulk polymer, and the scanning of the thin section is, therefore, carried out at that frequency. A commercial double-beam infrared spectrometer has been adapted for the purpose, and is capable of achieving a resolution of better than 100 μm in lateral scan. Figure 2 shows the expected and observed concentration profiles for a typical run. The value of the diffusion coefficient D , is

readily evaluated from the shape of the profile⁶. It is also possible to evaluate the concentration dependence of D , where it is significant. Interface resistance, if any, is revealed by discontinuities in the broadened concentration profile⁶. Values of D in the range 10^{-5} – 10^{-10} $\text{cm}^2 \text{s}^{-1}$ may be obtained in times of the order of 1–30 d, and the estimated errors are of the order of 15%.

We have studied the diffusion of various long-chain, n -alkyl amides in low density polyethylene at about the melting temperature. The dependence on temperature and chain length is summarised in Fig. 3. The discontinuity in the slope of the Arrhenius plot as the temperature is raised is probably the result of the breakdown of the crystalline lamellae in the polythene, which at temperatures below

Fig. 2 Concentration profiles. A, observed profiles: a, $t \approx 0$ (initial step function; $t = 54$ s, $C_0 = 0.5\%$ stearamide in low density polythene (LDPE), weight ratio); b, after time $t(t = 5.22 \times 10^4$ s., $T = 130^\circ \text{C}$; C_0 as in (a)). Both profiles scanned at $1,660 \text{ cm}^{-1}$, an amide absorption frequency. B, calculated profiles⁶.

about 80°C comprise some 60% of the polymer; this leads to a decrease in the tortuosity of the path taken by the amide chains in the amorphous polymer regions, over and above the usual temperature dependence.

The diffusional behaviour of longer molecules in polymeric matrices is being explored.

Fig. 1 Outline of experimental procedure: a, Specimen I—pure polymer and specimen II—polymer + diffusant, dispersed uniformly (about 0.1–1% w/w); b, specimen I and II joined together; c, slice removed from centre of composite; d, slice scanned in x direction for concentration profile. e , Extinction coefficient of the diffusant at the chosen infrared wavelength, and the concentration $C(x)$ as x varies is recorded directly (Fig. 2) using a linear-log converter.

Fig. 3 Variation of the diffusion constant, D , of stearamide in LDPE as a function of temperature, T , about the melting region of the polymer: A, amorphous regime; S, semicrystalline regime. Inset, Diffusion constants, D , of $\text{CH}_3(\text{CH}_2)_n\text{CONH}_2$ in LDPE as a function of n , at 118°C . D decreases as diffusant length increases.

We thank ICI Plastics Division (Welwyn) for preparing the materials, and one of us (J.K.) thanks Dow Corning Chemicals for a maintenance grant. We are also grateful to Professor D. Tabor for encouragement.

Palaeotemperatures from tree rings and the D/H ratio of cellulose as a biochemical thermometer

DENDROCHRONOLOGY can provide sequences of tree rings from various parts of the world. The wood making up these rings can be accurately dated to ± 1 yr. Samples can be obtained going back a considerable time, for example wood from *Pinus aristata* (Bristle Cone Pine) trees can be obtained which goes back beyond 9,000 yr BP. If the isotopic ratios of the elements in the individual constituents in the wood contain a record of past climate, it may enable a curve of a climatic variable like temperature to be determined on a time base accurate to ± 1 yr.

One might expect the biochemical pathways leading from CO_2 and water to the compounds that make up the wood to have isotopic effects. The question is whether the isotopic effects have significant temperature coefficients. If they do, one would have in effect a "biochemical thermometer". Here we report the existence of such a biochemical thermometer.

To study how the isotopic composition of the constituents of wood varies with temperature we have studied wood laid down during the course of one year by a *Pinus radiata* (Monterey Pine) tree growing in Hamilton, New Zealand. This particular system was chosen because at this location *P. radiata* grows throughout the year^{1,2}. Wide rings (2 cm) are laid down which enables different parts of the ring, and therefore wood laid down at different temperatures, to be sampled.

The isotopic composition of the atmospheric precipitation varies only slightly between winter and summer (about 20‰) in deuterium content³ so that any temperature effects are not masked by changing isotopic composition of the atmospheric precipitation during the year. During the year in Hamilton both the monthly mean maximum daily temperature and the monthly mean daily temperature vary through a cycle with an amplitude of 10°C . Thus the method enables even small temperature-induced isotopic effects to be detected.

In Fig. 1 we present a plot of the deuterium/hydrogen (D/H) ratio of the C-H hydrogens of cellulose across two rings laid down during the period 1919–20 by a *P. radiata* tree growing in Hamilton, New Zealand. Cellulose was prepared by the standard techniques of wood chemistry (see for example ref. 4). Before the cellulose was combusted the exchangeable hydrogens on the hydroxyl groups were brought to a standard D/H by equilibration with water of known D/H (7 d, 95°C). The results are reported in per mille deviation from standard mean ocean water⁵. The system is at least 30‰ depleted in the summer as compared with the winter and seems to record the annual temperature cycle. It should be noted that the isotopic composition of the cellulose varies in the opposite direction to the isotopic composition of the atmospheric precipitation, which is more depleted in deuterium in the winter and less depleted in the summer. Thus the effect could not be the result of the changing of the isotopic composition of the precipitation. Similarly the results could not reflect changes in the isotopic composition of cell sap since cell sap would, if anything,

Fig. 1 Variation in isotopic ratio of the C-H hydrogens in cellulose across tree rings.

become less depleted in deuterium in summer due to greater evapotranspiration associated with higher temperatures and lower humidity. It is therefore concluded that the D/H ratio of cellulose in the wood of *P. radiata* changes with temperature due to the temperature effects on one or more of the biochemical reactions leading to cellulose. Taking into account the isotopic variations of the atmospheric precipitation we obtain a temperature coefficient for the C-H hydrogens of cellulose of -5% per $^{\circ}\text{C}$.

Most probably this change reflects the air temperature since it is the biochemical pathways leading to the synthesis of the sucrose in the leaves which lead to the formation of the C-H bonds. The sucrose is translocated to the trunk where it is converted to cellulose. If it is indeed a temperature effect on the biochemical steps leading to the synthesis of sucrose, then the effect described in this communication should be found to occur generally in C-3 plants. The temperature coefficient of this biochemical thermometer could enable past temperature measurements to be measured to better than 0.1°C which should be more than adequate for studying past climate changes.

The other isotopes both in cellulose and in the other compounds in wood are being studied and will be reported elsewhere.

We thank Dr C. H. Hendy for help, the New Zealand Institute of Nuclear Sciences for allowing the use of their mass spectrometer and the New Zealand Universities Grants Committee for financial support.

Stability of Lotka-Volterra systems

NONLINEAR systems are very often studied in terms of simple mathematical models. The Lotka-Volterra equations provide such a model and have been used to study physical, chemical, ecological and social systems¹. An important question in the analysis of these equations is the stability of the equilibrium values of the interacting variables. Most work with Lotka-Volterra models has considered only neighbourhood stability against small perturbations away from equilibrium. The question of global stability when large perturbations from equilibrium are involved has only been analysed in a few special cases². We establish here that for the general Lotka-Volterra models local stability ensures global stability (asymptotic stability in the large). This result provides justification for the work that has been and is being done^{2,3} on linearised versions of the Lotka-Volterra models.

Our emphasis here will be on ecological systems: we consider a set of interacting biological species, but that does not restrict the analysis. If N_i is the biomass (or population) of species i , it changes with time t according to the generalised Lotka-Volterra equations

$$dN_i/dt = N_i \left(b_i + \sum_j a_{ij} N_j \right)$$

Here b_i are growth rates in the absence of interactions, and a_{ii} and a_{ij} ($i \neq j$) are intraspecies and interspecies interaction coefficients, respectively. We make no assumption about the

elements a_{ij} , except that they are real. Equilibrium values of the biomass, N_i^* , are defined by $dN_i/dt = 0$, or

$$b_i = - \sum_j a_{ij} N_j^*$$

We consider 'feasible' models, where all $N_i^* > 0$.

A local stability analysis is carried out by introducing small perturbations $y_i = (N_i - N_i^*)$, and obtaining a linear system $dy/dt = Ay$. Here y is the vector of y_i , and the 'community matrix' A has elements $(a_{ij} N_j^*)$. This system is stable, or equivalently the matrix A is stable, if all of the eigenvalues of A have negative real parts. The stability of A guarantees the local stability of the system about the equilibrium values N_i^* .

To examine global stability, we first introduce variables x_i through the substitution $N_i = N_i^* \exp(x_i)$. The x_i then obey the equation

$$dx_i/dt = \sum_j a_{ij} N_j^* [\exp(x_j) - 1]$$

Let x be the vector of x_i . Consider the function⁴

$$V(x) = \sum_i [\exp(x_i) - x_i - 1]$$

Observe that $V(x)$ is positive definite, continuously differentiable, and that $V(x) \rightarrow \infty$ as $|x| \rightarrow \infty$. The time derivative is

$$dV(x)/dt = \sum_{i,j} [\exp(x_i) - 1] a_{ij} N_j^* [\exp(x_j) - 1]$$

Now, if the derivative dV/dt is negative definite, the function $V(x)$ would be a Lyapunov function for the system, and would ensure global stability about the equilibria N_i^* .

The conventional way of writing quadratic forms is in terms of a symmetric matrix. So we define a symmetric matrix $B = (A + A')/2$, where the prime indicates the transposed matrix. Then we rewrite dV/dt as a quadratic form with the elements of B , b_{ij} , as

$$dV/dt = \sum_{i,j} [\exp(x_i) - 1] b_{ij} [\exp(x_j) - 1]$$

Now if B is a negative definite matrix, dV/dt is negative definite, and V is a Lyapunov function.

The theorem of Lyapunov⁵, states that a matrix A is stable (in the sense that the real parts of its eigenvalues are all negative), if, and only if, there exists a positive definite matrix C such that $(CA + A'C)$ is negative definite. We choose $C = I/2$ where I is the unit matrix. With this choice, our earlier matrices A and B are related by $B = (CA + A'C)$. Thus the theorem states that local stability (stability of our matrix A) occurs if, and only if, B is negative definite. And the negative definiteness of B makes $V(x)$ a Lyapunov function, ensuring global stability.

Thus for the general Lotka-Volterra systems, local stability implies global stability, and vice versa. This result is a happy consequence of the general form $dN_i/dt = N_i F_i(N)$ and the linearity of the F_i . This result does not apply to situations where the 'community matrix' A is critical, that is, has eigenvalues with vanishing real parts. The special cases mentioned earlier for which global stability has been studied follow from the insertion of specific assumptions about the interaction coefficients. The implications for any specific system must of course be considered within the definite limitations of the Lotka-Volterra model as a representation of reality.

Recovery process of the sensitive plant

THERE is a long history of study of the unusual behaviour of the 'sensitive plant', *Mimosa pudica* L., stretching back to the *Enquiries into Plants*, written by Theophrastus in about 300 BC. A large literature has built up, much of which can be traced from the papers of Pickard¹, Sinyukhin and Gorchakov², and Weintraub³. In spite of this, very little work seems to have been done on the detailed kinematics of the recovery of the plant following a collapse. We report here the results of a study of the recovery of the primary petiole after seismonastic stimulation, that is, after collapse induced by a blow.

Plants used in this study were all grown from seed obtained from commercial seedhouses. The temperature was kept in the range $21 \pm 3^\circ\text{C}$ by suitable thermostatic controls. The lighting was supplied exclusively by a battery of eight 35-W fluorescent tubes mounted horizontally 24 cm above the plant pots. The sequence used was about 12 h light followed by 12 h darkness, the dark period being from 1700 to 0500. Plants were investigated at various ages in the range 1–18 months. They were grown in John Innes number 2 mixture, germinated in closed polythene containers and then transplanted into 2-inch pots.

Preliminary films of the collapse and recovery of plants taken 'end-on' to various primary petioles showed that the motions of the latter were always planar, although the motions of the secondary pinnae were more complex and sometimes gave an illusion of non-planar motion of the primary petiole. It was therefore convenient to place the plant in front of a vertical screen covered with 1-mm graph paper and orientate it so that the plane of motion of the primary petiole on which attention was to be focused was roughly parallel to the screen. A Sankyo CME 660 Super-8 cine camera was mounted so that its optical axis was roughly normal to the screen and passed close to the primary pulvinus connecting the stem of the plant to the primary petiole of interest. Preliminary experiments showed that the collapse takes a couple of seconds, whereas the recovery can take an hour or more. The camera was therefore run at its normal speed of 18 frames s^{-1} while the plant was being stimulated and collapsing, but thereafter only one frame was used every 5 s to obtain time-lapsed film of the recovery. As a check on the timing a stopwatch calibrated in 0.1-s intervals was mounted near the plant and filmed with it.

Since in most cases the primary petiole is approximately straight at all times the angle θ which it makes with the horizontal provides a quantitative measure of its geometrical condition. The graph paper on the screen was of assistance in measuring this angle. Any error in its measurement due to the direction of observation not being quite normal to the plane of motion would be small and would not affect either the general form of the θ -time curves or the periods of any oscillations contained in these.

Detailed observations were made of numerous collapses and recoveries using the plants at various ages and at a variety of times of day. The collapse process, which was always complete within 2–3 s, showed no particularly surprising features (detailed quantitative study will be reported elsewhere). The recovery process on the other hand, which usually took about an hour for completion, showed some rather unexpected features. The curve of θ against time for the recovery could take any one of three different forms which showed strong similarities to the displacement-time curves for an unforced damped harmonic oscillator. The first two forms (Fig. 1a and b) are similar to the two possible types of behaviour of a heavily damped harmonic oscillator, and accounted for 10 and 30%

Fig. 1 Examples of the three types of recovery: a, heavily damped mode (undershooting type); b, heavily damped mode (overshooting type); c, lightly damped mode.

of the observed recoveries, respectively—referred to jointly as the heavily damped mode. The third form (Fig. 1c) is similar to the lightly damped harmonic oscillator curve. The period of oscillation was typically about 15 min. It accounted for the remaining 60% of observed recoveries. This similarity to the damped harmonic oscillator does not extend to the fine detail. In the lightly damped mode, for example, the successive displacement maxima and minima do not obey the log. dec. rule. In view of the complex internal structure of the primary pulvinus it is not surprising that the response should deviate somewhat from that of a damped harmonic oscillator: the surprise is that it should show any resemblance to it at all. In fact it seems quite likely that the system can be modelled by the usual spring-mass-dashpot system with some simple nonlinearities imposed—for example, anisotropic damping.

In addition to the main observation that a primary petiole behaves in a manner resembling a damped harmonic oscillator a number of other interesting facts emerged from our study. First, different primary petioles of the same plant can recover by way of different modes at the same time. Second, a given petiole at a given age always recovers by way of the same mode. If this mode happens to be the heavily damped one, however, its type may change. Third, on the first stimulation after a long rest period (say, at least 24 h) the final equilibrium position reached differs from that before stimulation, but immediate restimulation produces no further change in the equilibrium position. Finally, for a given petiole recovering by way of the lightly damped mode the period of oscillation is greater on second and subsequent stimulations than on the first after a long rest period. In a typical case we found that the initial period was about 15 min but that this increased by about 30%

on the second stimulation with little further change on the third.

Odontoid processes in pipefish jaws

ABSENCE of jaw teeth of any kind has been considered a familial character in pipefishes (Syngnathidae)^{1–3}, and their feeding mode has generally been described as a picking or sucking process resulting from rapid intake of water through the elongate snout^{4,5}. During systematic studies of Indo-Pacific syngnathids, we have found toothlike processes on the premaxillae and dentaries in three genera of abdominal-pouch pipefishes (Gastrophori). These structures (Fig. 1) are best developed in *Choeroichthys sculptus* (Günther) and *C. brachysoma* (Bleeker) where they are readily seen under $\times 30$ magnification in all subadults and adults. In *Syngnathoides* Bleeker (dentaries only) and a newly described genus⁶, they are inconspicuous, and best seen in cleared and alizarin-stained material.

Histological sections (from *Choeroichthys sculptus*) show no evidence of enamel, pulp cavity or basal differentiation in these processes and they appear to be odontoid projections of bone, rather than true teeth. Nevertheless, location and gross morphology suggest that they serve as functional teeth, and that they may be used in browsing or some other previously unreported mode of pipefish feeding. Data on food items are unavailable, but the habitats of these forms lend some support to this

Fig. 1 Odontoid processes of *Choeroichthys sculptus*. a, Right premaxilla, maximum length about 0.8 mm; b, mandibles, maximum length about 0.9 mm. Arrows indicate 'teeth'.

assumption. All *Choeroichthys* species and the undescribed genus are associated with coral or rocky bottoms; *Syngnathoides*, monotypic, is reported to live on weeds³. Each of these habitats would provide suitable niches for grazing pipefishes.

These odontoid processes constitute a newly recognised character of systematic importance and may prove significant in studies of pipefish phylogeny.

Corpus allatum and ovarian growth in a polymorphic paedogenetic insect

IN parthenogenetically reproducing *Aphis craccivora* Koch, ovarian growth is initiated before birth and continues throughout larval life¹. Consequently, maintenance of the juvenile form and reproduction occur simultaneously in this insect. The corpus allatum has been shown to be active in both these processes in other insects where ovarian growth does not commence until after the larval stages are completed². To elucidate the role of the corpus allatum in the two simultaneous processes in *A. craccivora*, I have studied the gland and ovarian development during the larval stage. Both apterous and alate aphids were used as these two morphs have a different ovarian growth pattern in *A. craccivora*¹.

Aphid ovaries were examined from birth to the onset of larviposition by dissection in distilled water after rapid fixation in Gilson's fluid. An index of ovarian development was found by calculating the total length of oocytes and embryos present in the body. Aphid heads were fixed in Gilson's fluid, sectioned sagittally at 6 μ m and stained with Ehrlich's haematoxylin. Corpus allatum nuclei were measured with an eyepiece micrometer and the mean nuclear size was calculated using the mean product of the long and short diameters of four nuclei in the gland³.

The mean nuclear size of the corpus allatum was positively correlated with the ovarian index in both apterae ($r = 0.91$, $P < 0.05$) and alatae ($r = 0.95$, $P < 0.05$) up to the onset of larviposition. This correlation was maintained in each morph even though their ovarian development is out of phase. Apterous have a greater corpus allatum mean nuclear size and ovarian index than alatae during larval life until the adult moult when larviposition occurs in apterae. But the two parameters continue to increase in alatae until larviposition occurs approximately 2 d after the adult moult.

The growth of the corpus allatum during the larval stage was enormous compared with that of body length and head width. Corpus allatum volume increased elevenfold from birth to the final moult while body length and head width showed a fourfold increase. The mean length of the terminal ovarian follicle increased tenfold in the same period.

My results provide strong evidence that the corpus allatum in *A. craccivora* is simultaneously involved in ovarian growth and maintenance of the juvenile form during the larval stage. Further proof for the extra role of the corpus allatum during larval life in *A. craccivora* compared with non-paedogenetic insects is given by the measurements of relative growth of the gland and other body parts. A comparative study of several

holometabolous and hemimetabolous insects² showed little growth of the corpus allatum during the larval stage compared with the increase in body length and head width—the opposite result to that obtained with the paedogenetic *A. craccivora*. As ovarian growth and maintenance of the juvenile state are simultaneous processes in this aphid it is likely that only one corpus allatum hormone is involved in both processes.

The comparison of apterous and alate aphids correlates well with previous studies on the role of the corpus allatum in wing polymorphism⁴ and the total involvement of the gland in aphid physiology is now more apparent. The higher corpus allatum activity in apterae during the larval stage promotes faster ovarian growth and preserves the juvenile form, while in alatae, the development of wing buds and reduced ovarian growth are both coincident with a lower corpus allatum activity.

Silent allele as genetic basis of fucosidosis

SEVERAL individuals have been recognised as having an almost complete deficiency of the lysosomal hydrolase α -L-fucosidase (EC 3.2.1.51) in their tissues and body fluids¹⁻⁷. This condition (designated fucosidosis) is associated with the accumulation of fucose-containing glycolipids and glycoproteins in various tissues¹⁻⁵. The clinical manifestations include coarse facial features, progressive psychomotor regression, susceptibility to respiratory infections and severe neurological signs, including generalised spasticity. Two distinct forms of fucosidosis (types 1 and 2) have been recognised⁷. Both are characterised by a virtually complete deficiency of α -fucosidase activity when assayed with artificial substrates. Physical and mental deterioration, however, proceeds far more rapidly in type 1 and these patients do not survive beyond early childhood. Type 2 patients can survive to adult life³. Additional features which distinguish the two forms of the disease are the presence, in type 2 only, of the skin lesion, angiokeratoma corporis diffusum, and an elevation in type 1 only, of the NaCl concentration in sweat⁷.

We have described a common polymorphism of α -fucosidase in the North American population⁸. Using isoelectric focusing in acrylamide gel and a specific staining technique we were able to distinguish three distinct phenotypes in neuraminidase-treated leukocyte extracts from different normal individuals (Fig. 1). Treatment with neuraminidase converted the six or more isozymes present in the original extract to one of the relatively simple patterns shown in Fig. 1, apparently by removing sialic acid residues from the more acidic isozymes and thus converting them into the less acidic forms⁹. Family studies showed that the three common phenotypes were attributable to the existence of two codominant alleles at a single, autosomal gene locus. These alleles were designated Fu^1 and Fu^2 . Thus, individuals of phenotypes Fu^1 , Fu^2 and Fu^{2-1} had the genotypes Fu^1Fu^1 , Fu^2Fu^2 and Fu^2Fu^1 , respectively.

We have studied the segregation of these two common alleles at the α -fucosidase gene locus in the family of two brothers affected with fucosidosis 2. The results have thrown some light on the genetic basis of the disease. The pedigree of the patients' family is shown in Fig. 2. The three phenotypes Fu^1 , Fu^{2-1} and Fu^2 were all observed in leukocytes from family members. None of the α -fucosidase isozymes was detected in leukocytes, cultured long term lymphoid lines, fibroblasts or serum from the two affected children. With this exception,

Fig. 1 Isozyme composition of the three common α -fucosidase phenotypes after isoelectric focusing of neuraminidase-treated leukocyte extracts in acrylamide gel⁸. *a*, Part of an acrylamide gel stained with 4-methylumbelliferyl- α -L-fucoside and photographed in ultraviolet light. Four samples shown have the phenotypes (from left to right) Fu^1 , Fu^{2-1} , Fu^{2-1} and Fu^2 . *b*, Diagrammatic representation of the three common phenotypes. Arrows show the approximate pH range within which the various isozymes focused.

isozyme patterns among family members did not differ from those seen in the general population. There exist within this family, however, two patterns of inheritance of α -fucosidase phenotypes which are clearly not consistent with the simple segregation of two codominant alleles. The first incompatibility is between the paternal grandmother (I5) of the two affected children and her daughter (II4), with the mother having the Fu^2 phenotype and the daughter the Fu^1 phenotype. A photograph of the isozymes seen in leukocytes from these individuals is shown in Fig. 3. In the normal course of events the daughter would inevitably have received an Fu^2 allele from her mother and would therefore have an Fu^2 or Fu^{2-1} phenotype, depending on whether she received an Fu^1 or Fu^2 allele from her father.

If one rules out such unlikely events as fresh mutation or non-biological parenthood (particularly unlikely as it is mother and daughter who are incompatible) then the presence of a silent (or 'null') allele at the α -fucosidase locus is the only satisfactory explanation for the observed segregation of phenotypes. This allele, which we will call Fu^0 , is silent in the sense that its product (if any) is not detectable by the assay methods used in this study. Having introduced the Fu^0 allele the explanation for the observed pattern of inheritance becomes straightforward. The paternal grandmother (I5) has the genotype Fu^2Fu^0 and consequently an Fu^2 phenotype. Her daughter (II4) received an Fu^0 allele from her mother and a normal Fu^1 allele from her father, resulting in the genotype Fu^1Fu^0 and an Fu^1 phenotype (Fig. 2).

The second example of apparent incompatibility between parent and child is between I2, who has an Fu^2 phenotype, and his son (III) who is Fu^1 . This situation can also be resolved by proposing that a silent allele is present. In this case the father must have the genotype Fu^2Fu^0 , resulting in an Fu^2 phenotype, whereas the son has the genotype Fu^1Fu^0 , having received a normal Fu^1 allele from his mother (II) and an Fu^0 allele from his father.

Because of the unusual inheritance of α -fucosidase phenotypes within this family we examined the segregation of phosphoglucomutase (locus 1), esterase D and red cell acid phosphatase phenotypes. All these enzymes are coded by two or

more common alleles in human populations¹⁰⁻¹². Throughout the family the inheritance of these polymorphic enzymes was completely normal and consistent with the relationships shown in Fig. 2.

If a silent allele is segregating at the α -fucosidase locus within this family it is likely that the two children affected with fucosidosis and with virtual absence of α -fucosidase activity, are in fact homozygous for this allele. If this is so then their parents must be carriers of Fu^0 and must therefore have either an Fu^1 or Fu^2 phenotype. An Fu^2 -1 phenotype is clearly impossible. As shown in Fig. 3, the two parents (II5 and II6) have the phenotypes Fu^2 and Fu^1 , respectively, presumably with the genotypes Fu^2Fu^0 and Fu^1Fu^0 .

Based on the assumptions that the three alleles Fu^1 , Fu^2 and Fu^0 are segregating within this family and that individuals marrying into the family have two normal alleles, we have been able to derive unambiguous genotypes for most of its members. In three cases, however, it was not possible to do this on the basis of phenotyping alone. Individuals I3, II8 and III3, all of whom have the Fu^1 phenotype, could be of genotypes Fu^1Fu^1 or Fu^1Fu^0 , with equal probability. In these cases the genotypes shown in the pedigree were assigned on the basis of the α -fucosidase activity of peripheral leukocytes, on the assumption that individuals carrying the silent allele should have a lower level of activity than individuals with two normal alleles. A comparison of obligatory carriers of Fu^0 (that is, I2,5,7 and II1,4,5,6) with normals (that is, II1,4,6 and II2,3,9) supports this assumption. Average α -fucosidase activity in obligatory carriers of Fu^0 was 132 ± 27 nmol per h per mg protein, whereas in normals the equivalent value was 243 ± 59 . Leukocyte activities for individual members of the family are shown in Fig. 2. The present results support previous findings which showed that a high proportion of carriers for fucosidosis (that is, heterozygotes for Fu^0) could be detected by enzyme assay methods¹³.

In each branch of the family the Fu^0 allele must have been passed down by way of the grandmother (I5 and I7) as both grandfathers are Fu^2 -1 heterozygotes and must therefore have two normal alleles. Note that whereas the two grandfathers are of Polish and German descent, the two grandmothers are both of Southern Italian parentage. Of six other families reported with fucosidosis¹⁻⁶ (four with type 1 and two with less severe type 2), three have been of Southern Italian origin (two type 1 and one type 2).

In the family described, the presence of a silent allele at the

Fig. 2 Pedigree showing segregation of common alleles Fu^1 and Fu^2 and the silent allele Fu^0 in the family of two sibs with α -fucosidase deficiency. Numbers 1, 2 and 2-1 are α -fucosidase phenotypes determined by isoelectric focusing. Leukocyte α -fucosidase activities (nmol 4-methylumbelliferone released per h per mg protein) are shown in parentheses. Two affected children are indicated by arrows. A clinical description of these two children has been presented elsewhere⁷.

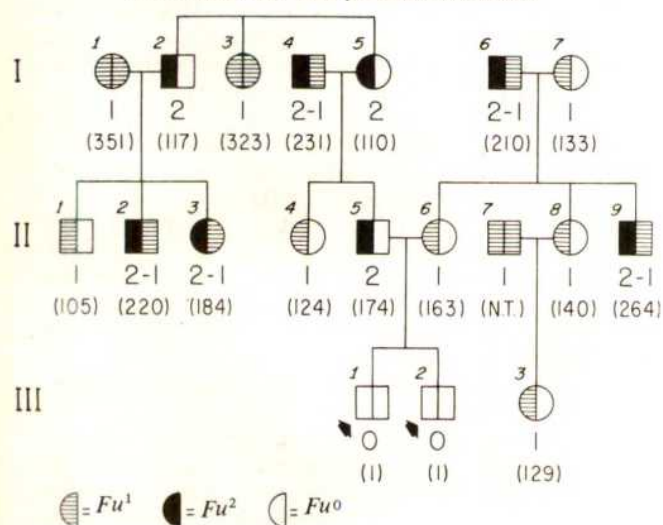

Fig. 3 Isozyme composition of α -fucosidase in leukocyte extracts from some members of the family shown in Fig. 2. Pedigree number of each individual is shown. α -Fucosidase phenotypes (from left to right) are Fu^2 -1, 2, 2-1, 1, 1, 2 and 1.

α -fucosidase locus has been deduced from apparent anomalies in the inheritance of two normal alleles at that locus. Although mutations at loci coding proteins required for activation, stabilisation or regulation of α -fucosidase could certainly account for a reduction in enzyme activity in the heterozygous state and a deficiency in homozygotes, such mutations cannot explain the qualitative abnormalities in the inheritance of the three common α -fucosidase phenotypes described here. On the other hand, a mutation within the structural locus for α -fucosidase, resulting in an inactive or silent allele at that locus, provides a satisfactory explanation for both the qualitative and quantitative aspects of α -fucosidase inheritance within this family.

Rare silent alleles have been detected during studies on the inheritance of polymorphic proteins in normal families¹⁴. Only recently, however, have family studies of this type been used to implicate structural gene mutations as a cause of human disease^{15,16}. As it has been estimated¹⁷ that 25-30% of all human enzymes have common polymorphisms detectable by electrophoresis alone, studies of this type should be widely applicable to the study of inherited enzyme deficiencies.

Phagocytosis and cytotoxicity by a macrophage tumour and its cloned cell line

MACROPHAGES found in lymphoid and other tissues are defined by adherence, staining, morphology and rapid pinocytosis. Subtypes of macrophage-like cells have been distinguished on the basis of density and functional properties¹⁻³. Immune macrophages⁴ and normal macrophages in the presence of specific antiserum⁵⁻⁸ will lyse relevant target cells, and can phagocytose cells by an independent mechanism⁹⁻¹², but it has not been shown that the same cell type can carry out both functions.

We have described a murine reticulum cell sarcoma (J774), whose ascites form has the macrophage properties of adherence, morphology, receptors for immunoglobulin, and antibody-dependent lysis of target cells¹³. The tumour-cell pellet contains 10–50 µg lysozyme per 10⁷ cells, and as much as 200 µg ml⁻¹ of the enzyme is found in the ascitic fluid. This tumour has now been adapted to culture and cloned. Both the cell line and ascites cells exhibit phagocytosis and lysis of target cells, dependent on specific antibody, but the cell line is mainly phagocytic, and the fresh tumour is mainly cytotoxic. The result is influenced greatly by the method of assay, and the effector cell population can be rapidly switched from one mode of attack to the other. Cultured cells produce typical ascites when reintroduced into mice, but require several days *in vivo* to change from high levels of phagocytosis to cytotoxicity.

J774 ascites cells are highly cytotoxic in the presence of specific antiserum lysing 50% of target red blood cells (RBCs) in 4 h at an effector target cell ratio of 2 : 1 (Fig. 1a). Low but significant lysis is seen even at a ratio of 1 effector cell to 10 RBCs. We have shown¹³ that the small number of host peritoneal cells contained in the ascites fluid are not responsible for this killing effect. Only a small proportion of cells are phagocytosed in the same assay using tissue culture dishes. When the assay is performed in plastic tubes, the effector cells exhibit less cytotoxicity and much more phagocytosis, also dependent on specific antiserum. Wide tubes used to simulate the shallow fluid depth in culture dishes give results similar to narrow tubes. Tumour cells adhere more strongly to the dishes than tubes, and this may be a signal favouring cytotoxicity.

J774 ascites cells put into culture did not grow initially, and their cytotoxic activity gradually declined over several months. A cell line was derived after one passage back into mice, which grows partly adherent and partly floating, with a doubling time around 24 h. When subcultured separately, adherent and non-adherent cells will each generate the mixed cell population. The culture cell line also synthesises large amounts of lysozyme.

The cell line exhibits minor cytotoxicity but predominantly antibody-dependent phagocytosis (Fig. 1b). The adherent and non-adherent cells tested separately give identical results. The two culture types may represent different stages of the cell growth cycle, or a response to culture conditions, such as limited surface area, although the culture dish is not visibly crowded when floating cells appear. Most of the lysis or ingestion of RBCs occurs in the first 2 h of incubation, and radioactivity within the macrophage tumour cells is retained for more than 4 h thereafter. This culture line has been reinjected into mice many times, and the resulting ascites cells always show the strong antibody-dependent cytotoxic activity of the original tumour line (Fig. 1c).

The two effector mechanisms may be carried out by two different cell lineages coexisting in the ascites and culture populations. The growth conditions could thus influence which cell type and effector function dominated. Therefore, the culture line was cloned and tested. The cloned culture J774.1 mainly phagocytoses cells rather than lysing them (Fig. 1d), similar to the parent culture, and the ascites form of the cloned cell line mainly kills targets (Fig. 1e). Normal spleen cells, at

50-fold higher concentrations, have the cytotoxic capacity of ascites preparations, but exhibit no phagocytosis (Fig. 1f).

How rapidly can the effector cell population change its handling of antibody-antigen conjugates? Most of the killing or ingestion of RBCs by J774 occurs in the first 2 h either in the tube or dish assay using 0.5 RBCs per J774. J774 ascites cells were therefore incubated for 2 h at 37 °C in tubes which favoured phagocytosis, and then washed and tested for reaction with labelled RBCs in dishes. Most of the macrophage cells were recovered by vigorous pipetting. Preincubation alone in tubes has no effect on the subsequent ability of J774 to kill targets in dishes (90% of control killing shown by cells kept on ice during preincubation). With antiserum and 2 RBCs per J774, the subsequent killing activity was 70% of that for controls. When preincubated with antiserum and 10 RBCs per J774, during which 50% RBCs are phagocytosed with 95% of the macrophage cells containing at least one erythrocyte, the subsequent killing of newly added targets with antiserum was only 25% of that for controls. This high dose inhibition may be due to competition for macrophage surface receptor sites by antigen-antibody complexes, as well as to physiological changes resulting from massive phagocytosis.

Thus, the population of J774 effector cells can be rapidly and reversibly switched between two different mechanisms of handling target RBCs. But, the culture line still does not show the very high killing activity of the ascites preparation. To study this transition, we passaged culture cells into mice intraperitoneally and tested for antibody-dependent cytotoxicity during the next few days (Table 1). One day after *in vivo* passage, cells still resembled fresh cultured cells, whereas ascites passaged 1 d

Fig. 1 Cytotoxicity (open columns) and phagocytosis (hatched columns) by J774 effector populations. Assays were performed according to Walker and Demus¹² using 2×10^5 J774 cells or 10^7 spleen cells, 10^5 ⁵¹Cr-labelled sheep RBCs and 10 µl of 1:10 mouse anti-RBCs or 1:10 normal mouse serum¹³ in 1 ml volumes containing 5% heat inactivated foetal calf serum. Cultures were incubated 4 h in rocking tissue culture dishes (Falcon 3001) or stationary tubes (Falcon 2038). Plastic Petri dishes (Falcon 1008) gave less killing and phagocytosis, and large tubes (Falcon 2051), which more nearly duplicates the large area and short liquid depth of dishes, gave results identical to the small tubes. Very little effector activity was seen in assays using glass tubes. Antibody-dependent target lysis was determined by release of ⁵¹Cr to the medium, and phagocytosis by water-lysis resistant radioactivity in cell pellets corrected¹³ for control values with normal serum (about 7% lysis and 14% water-resistant counts). These control values were similar to those from incubations without mouse serum or in which effector cells were replaced by 10^7 chicken RBCs. Each result is the average of several experiments using duplicates, with standard errors $\leq 7\%$ of means. a, c and e, Ascites cells collected from mice at 10–20 d after intraperitoneal inoculation with 0.1 ml ascites fluid (a) or 10^7 culture cells (c and e). b and d, J774 cells growing in Eagle's medium containing 10% foetal calf serum, after more than 100 doublings of the population *in vitro*. The cells in d were cloned by limit dilution in a row of 8 wells inoculated with approximately 2 cells per well, only one well developing a colony of cells, which appeared as a single focus. f, Normal spleen.

Table 1 Transition from phagocytosis by culture cells to lysis by ascites cells

Cells	Days <i>in vivo</i>	Effector activity			
		Dish		Tube	
		Lysis	Phagocytosis	Lysis	Phagocytosis
Culture	0	6	31	0	48
	1	11	35	0	61
	3	15	21	2	55
	10-20	54	3	11	25
Ascites	1	41	13	0	31
	10-20	55	11	6	29

Effector cell activity was assayed as in Fig. 1. J774 culture cells were used directly (day 0), or 1-20 d after transfer to mice intraperitoneally. Ascites cells were used 1 d or 10-20 d after transfer to mice intraperitoneally.

in mice showed the typical ascites response. Three days after *in vivo* passage, the culture cells showed effector levels intermediate between the culture line and long term ascites. Ascites resulting from culture cells passaged 10-20 d in mice behave as typical ascites preparations.

We believe these experiments demonstrate that a single cell lineage of macrophages can both phagocytose cells without immediate release of labelled components and directly lyse antibody-coated target cells. The evidence includes: first, the unlikelihood of two different macrophage tumours originating in the same mouse (we have seen only two reticulum cell sarcomas among more than 500 tumours during a myeloma induction programme in which J774 occurred); second, the unlikelihood of two tumours coexisting through many animal and culture passages; third, the reversible shift from lysis by ascites preparations to phagocytosis by culture cells; and finally, identical results with a cloned cell line. The assay conditions largely determine which mechanism predominates. It is not clear, however, if the same cell can carry out both functions rapidly at the same time. The effector populations studied may be composed of subgroups at different stages of differentiation. The slow transition over several days from the phagocytosis exhibited by cells grown in culture to the predominant cytotoxicity of ascites cells suggests that changes in the total population occur after one or more rounds of cell division in *in vivo* or *in vitro* conditions. It will be interesting to see if normal macrophages stimulated by growth factors to divide in culture¹⁴ can be switched from cytolysis to increased phagocytosis. An SV40-transformed macrophage cell line described by Walker and Demus¹² *in vitro* shows a high level of phagocytosis similar to cultured J774. Another macrophage-like cell line derived from a methylcholanthrene-induced 'lymphoid' neoplasm has been described by Koren, Handwerger and Wunderlich¹⁵ as being highly active in killing target cells, although a comparison of target phagocytosis was not done.

The ability to manipulate a cloned line of cells with several effector functions will facilitate further understanding of the role of macrophages in immunity.

Resistance of *Trypanosoma cruzi* to killing by macrophages

CHAGAS' disease is a chronic debilitating illness, widespread in Latin America, caused by infection with the haemoflagellate, *Trypanosoma cruzi*. Antibodies to the organism, commonly present in both the acute and chronic forms of the disease, have generally been ineffective in protecting animals against infection^{1,2}. There is ample pathological documentation of the involvement of macrophages in Chagas' disease³⁻⁵ but unfortunately little is known about their function, or of the role of cell-mediated immunity in general. It has, however, been shown that passive transfer of immune spleen cells can protect mice against *T. cruzi* infection¹. Because macrophages serve as effector cells in protecting against intracellular parasites, we have studied the interaction of *T. cruzi* and macrophages *in vitro*. Preliminary experiments showed that at low parasite-macrophage ratios (for example 1) most cultures of normal uninduced mouse peritoneal macrophages could eliminate the infection and survive; in contrast, with higher ratios (for example 10), they were destroyed⁶. Mackaness⁷ has shown that macrophages can be 'activated' after immunisation and challenge with specific antigen to become non-specifically resistant to other infecting bacteria. We report here that nonspecifically 'activated' macrophages have heightened resistance to intracellular growth of *T. cruzi*, and suggest that its absence in normal macrophages is related to the ability of the parasite to escape from the phagolysosomes into the cytoplasm.

The Tulahuen and Ernestina strains of *T. cruzi* were supplied by Dr Franklin Neva of the National Institutes of Health, and cultured as described previously⁸. Normal macrophages were collected from the peritoneal cavity of C57BL/10.D2 mice by lavage with ice-cold Hanks' solution containing 5 IU ml⁻¹ of heparin. Macrophages which we term activated were obtained by immunising mice with living BCG (5 × 10⁶ Phipps strain, intraperitoneally) and challenging the mice 21 d later with 10⁷ BCG given intraperitoneally. The peritoneal macrophages were collected 3 d later.

The term activated macrophages has been used in the past to denote different, and not necessarily related properties, for example more rapid attachment and increased spreading on substrates, morphological changes such as highly developed membrane systems, increased lysosomal hydrolases and increased capacity to kill intracellular parasites and tumour cells. Yet, there was little to distinguish between normal and BCG-activated macrophages in terms of handling *T. cruzi* 2 h after infection; the number of organisms ingested, and their uptake into phagocytic vesicles were very similar (Fig. 1a and b and Fig. 2). While some killing of parasites was detectable as early as 2 h, by 24 h after infection at a parasite-macrophage ratio of 1 most ingested parasites were undergoing degradation intracellularly both in normal and activated macrophage populations, although at a ratio of 10 the activated macrophages seemed to be more advanced in digesting the organisms. It has been reported that living toxoplasmas can survive within mouse macrophages because they block fusion of primary lysosomes with phagocytic vesicles⁹; consequently, the Thorotrast labelling technique was used to visualise lysosomes.

Fig. 1 Fate of *T. cruzi* in normal and activated macrophages. Peritoneal macrophages from normal mice and from animals primed and challenged with BCG (activated) were cultured at 2×10^6 – 3×10^6 cells per ml in 10% foetal bovine serum on coverslips in Leighton tubes. To label phagocytic vacuoles and lysosomes, 24 h before infection or collection, macrophages were treated with a thorium dioxide (Thorotrast) suspension at a final dilution of 1:175. After washing, cultures were infected with 7-d cultures, primarily epimastigote forms, of *T. cruzi* at 1:1, 10:1 and 100:1 parasite-macrophage ratios. After 2 h, coverslips were washed three times with agitation to remove free swimming forms, and replaced with fresh medium and observed at 2, 24, 48, 72, 96 and 192 h after infection. Details for preparation of coverslips for electron microscopy have been described elsewhere⁸. *a*, *c* and *e*, Normal macrophages; *b*, *d* and *f*, activated macrophages infected at a parasite-macrophage ratio of 10. *a* and *b*, Taken 2 h after infection (primary magnification $\times 2,200$). Arrows indicate dark Thorotrast-containing vesicles (lysosomes) which have fused with phagocytic vesicles containing trypanosomes in both normal and activated macrophages. *c* and *d*, Taken after 96 h of infection (primary magnification $\times 1,320$) and indicate persistence of trypanosomes in the normal macrophages but complete elimination from the activated macrophages. Note the relative abundance of Thorotrast-containing lysosomes and vacuoles and enlarged Golgi region. Arrows indicate trypanosomes residing in the cytoplasm. *e* and *f*, Higher magnifications ($\times 3,520$) of 96-h infected macrophages. *e*, Trypanosomes in the cytoplasm of normal macrophages. Note absence of trypanosomes in Thorotrast-marked vesicles. *f*, Trypanosomal remnants, including kinetoplast within Thorotrast-containing vesicle within an activated macrophage.

With *T. cruzi* virtually all parasites entered through phagocytic vacuoles which is consistent with the observation that cytochalasin B diminished the number of organisms found within macrophages⁹. Fusion of Thorotrast-labelled lysosomes and vacuoles with *T. cruzi*-containing phagocytic vesicles occurred equally well in normal macrophages and in BCG-activated macrophages (Fig. 1*a* and *b*). On the basis of observation of cells infected for 2–24 h, it would be impossible to predict which cultures were likely to be more effective in clearing the infection.

When infected cultures were examined 4–6 d after infection, however, a considerable difference was observed in *T. cruzi* growth in normal relative to activated macrophages (Fig. 1*c* and *d* and Fig. 2). Virtually all macrophages in the BCG-activated population infected at parasite-macrophage ratios of 10 had killed and degraded the intracellular parasites. The cytoplasm consisted of Thorotrast-labelled lysosomes, hyperactive Golgi and developed membranes, with occasional remnants of trypanosomes (Fig. 1*d* and *f*). In contrast, normal macrophage populations showed extensive intracellular growth of the *T. cruzi* (Fig. 1*c* and *e*). Significantly, ultrastructural examination revealed that the parasites were proliferating within the cytoplasm of the cells and were no longer found in phagocytic vesicles. Essentially no Thorotrast could be seen surrounding the parasites, and only the outer membrane of the parasite could be observed with the tilting EM stage separating them from the cell cytoplasm.

It thus seems that *T. cruzi* can survive in normal macrophages

Fig. 2 Survival of intact *T. cruzi* in macrophages. Counts of intact trypanosomes were made on electron microscopic scanning of 100 consecutive macrophages from 24-h or 96-h cultures infected at a ratio of trypanosomes-macrophage of 10:1.

by escaping from phagocytic vacuoles into the cytoplasm where, presumably, macrophages have no specially developed mechanisms for killing. Even though most parasites are probably killed in normal macrophages, the small number which survive seem capable of escaping and proliferating intracytoplasmically. Nonspecific activation of macrophages, as by BCG, seems to enhance the efficacy of killing in these cultures.

The distinctness of the patterns of interaction between different protozoan parasites and host cells is emphasised by these studies. Although nonspecifically activated macrophages were more effective in killing *T. cruzi*, this has not been found

to be the case with *Toxoplasma gondii* unless specific antibodies¹⁰ or supernatants of activated lymphocytes^{11,12} were present. Mauel *et al.*¹³ observed that nonspecifically activated mouse macrophages were capable of enhanced killing of *Leishmania enriettii*, which is infectious for guinea pigs, but not mice, but not of *L. tropica*, which is infectious for mice.

Our results are consistent with the finding in bacterial systems⁷ that killing seems to be very rapid, whereas degradation may take longer. The only other instance of which we are aware in which protection against macrophage killing may be associated with growth of the organism free in the cytoplasm is that of human *Mycobacterium leprae*. In studies on the growth of the organism in lymph nodes draining foot pads of mice challenged with *M. leprae*, Evans and Levy^{14,15} observed that during the logarithmic growth phase of the organism, only one membrane seemed to separate the mycobacterium from the cytoplasm; in the plateau phase, presumably brought about by the development of cellular immunity in the host, it seemed that *M. leprae* was found in vacuoles containing an additional membrane, probably the lysosomal membrane. Together, these experiments emphasise (1) the importance of lysosomes in controlling intracellular parasitism; (2) the need to design chemotherapeutic agents able to act within lysosomes; (3) the possible efficacy of nonspecific, and ultimately of specific, immunisation in enhancing destruction of phagocytosed parasites.

Suppression of cell-mediated tumour immunity by *Corynebacterium parvum*

THE use of immunoadjuvants in tumour therapy is based largely on the concept that an increased level of specific immunity against tumour-associated antigens may be achieved by nonspecific stimulation of the immune system (for review see ref. 1). Among these adjuvants, *Corynebacterium parvum* has received much attention since it represents one of the most powerful stimulants of the reticuloendothelial system in mice², and is effective in inhibiting tumour growth in several animal tumour systems (for example, see refs 3–6). The mechanisms by which *C. parvum* interferes with tumour growth have not been established and the tumour protective effect of *C. parvum* has not been entirely consistent in all systems studied. An immunosuppressive effect of *C. parvum* has been demonstrated too. In mice, the *in vitro* lymphoproliferative

Table 1 Effect of injection of *C. parvum* on the *in vitro* secondary cytotoxic response of MSV-immune spleen cells against specific targets

Experiment no.	Source of spleen cells*	Effector cell–target cell ratio		
		50:1	25:1	12.5:1
1	MSV 30	62.8	44.4	27.1
	MSV 30	58.6	38.1	16.9
	MSV 30, CP 7	16.5	9.2	7.3
	MSV 30, CP 7	13.1	9.3	4.5
2	MSV 30	80.6	70.3	50.8
	MSV 30	72.6	63.1	43.3
	MSV 30	75.5	62.6	44.6
	MSV 30, CP 7	24.7	18.4	10.8
	MSV 30, CP 7	28.7	17.2	11.2
	MSV 30, CP 7	26.6	15.0	10.9

*Mice were tested 30 d after injection of MSV and 7 d after intraperitoneal injection of 1.4 mg CP. A total of 20×10^6 spleen cells was cultured with 1×10^6 mitomycin C-treated RBL-5 ascites lymphoma cells for 5 d.

Surviving cells were counted by Trypan blue exclusion and the cytolytic capacity of the spleen cells against RBL-5 cells was tested in a 4-h ⁵¹Cr release assay of cytotoxicity (ref. 12) at various effector cell–target cell ratios. Results represent the mean percentage ⁵¹Cr release of quadruplicate samples of individual mice in two representative experiments. Spleen cells cultivated for 5 d in the absence of RBL-5 cells showed 5–10% cytotoxicity at the 50:1 ratio and less than 5% cytotoxicity at the two lower ratios.

responses to mitogens and to alloantigens were depressed after injection of *C. parvum*. It remains to be determined, however, whether a defect measured by these general tests of T lymphocytes may also represent an indication of depressed cell-mediated immunity against tumour cells.

A specific secondary *in vitro* cytotoxic response of immune spleen cells has been demonstrated in a murine sarcoma, virus (Moloney)–(MSV)–induced tumour system⁸. The secondary response was much stronger than the primary cytotoxic response in this tumour system and in its kinetics correlated better with the status of *in vivo* immunity as determined by transplantation protection studies. We now report that injection of CP markedly inhibited the ability of spleen cells to undergo an *in vitro* secondary cytotoxic response, suggesting that treatment with CP causes a depression of specific anti-tumour cellular immunity.

Primary MSV tumours were induced in C57BL/6N mice by intramuscular injection of virus (all details of this tumour system as used in our laboratory are given in refs 9–11). Tumours usually regressed after 21 d and mice were then immune to rechallenge with MSV or cross-reacting leukaemia cells for extended periods. A secondary cytotoxic response of immune lymphocytes could be elicited either *in vivo*¹² or *in vitro*⁸. For testing the *in vitro* secondary cytotoxic response, spleen cells from mice 30 d after virus injection (designated MSV 30 spleen cells) were cultivated in the presence of mitomycin C-treated ($100 \mu\text{g ml}^{-1}$, 30 min) RBL-5 ascites lymphoma cells which have been shown to possess the relevant antigens of the MSV system¹⁰. A total of 20×10^6 spleen cells and 1×10^6 RBL-5 cells was cultivated for 5 d in 5 ml of medium RPMI 1640 (supplemented with 5% foetal bovine serum and 5×10^{-5} M 2-mercaptoethanol) in 16-ounce tissue culture flasks. Subsequently, the sensitised spleen cells and appropriate controls were tested for their ability to lyse RBL-5 cells in a 4-h ⁵¹Cr release assay (details of this assay are in ref. 9).

As Tables 1–3 show, a vigorous cytotoxic response of MSV 30 spleen cells could be demonstrated after stimulating them *in vitro* with mitomycin C-treated RBL-5 cells. There was only little activity when MSV 30 spleen cells were cultivated for 5 d in the absence of RBL-5 cells (Tables 2 and 3). The response of normal spleen cells to RBL-5 cells was also very low in our culture conditions (data now shown).

To investigate the effect of *C. parvum* (formalin-killed CP vaccine (N6314) batch 1 PX 398, Burroughs Wellcome, Research Triangle Park, North Carolina) on the *in vitro* secondary

cytotoxic response of MSV 30 spleen cells, two different protocols were used. In the first, 1.4 mg *C. parvum* was injected intraperitoneally into MSV-immune mice 23 d after virus inoculation and spleen cells were tested 7 d later for their activity in the *in vitro* assay of the secondary cytotoxic response. Representative experiments are shown in Table 1. Treatment by *C. parvum* decreased the cytotoxic response of immune spleen cells by more than 70%. This was equally observed at effector cell-target cell ratios of 50:1, 25:1, and 12.5:1.

In the other protocol, 1.4 mg *C. parvum* was injected intraperitoneally into normal C57BL/6 mice, and after 8–10 d their spleen cells were mixed with MSV 30 spleen cells, to determine their effect on the *in vitro* secondary cytotoxic response. Various numbers of spleen cells from mice injected with *C. parvum* were mixed with a fixed number of MSV 30 spleen cells. As controls, spleen cells from normal untreated mice were added. As Table 2 shows, the addition of normal spleen cells at three different doses had little or no suppressive effect on the cytotoxic response of MSV 30 spleen cells. A significant depression was seen, however, when *C. parvum* spleen cells were added to MSV 30 spleen cells.

Table 2 Effect of spleen cells from *C. parvum*-injected mice on the *in vitro* secondary cytotoxic response of spleen cells from mice immune to MSV

Source and number of cells added to 20 × 10 ⁶ MSV 30 spleen cells*	Stimulating cells	
	None	RBL-5
None	8.3†	75.8
40 × 10 ⁶ normal spleen cells	6.6	63.7
20 × 10 ⁶ normal spleen cells	7.9	68.8
10 × 10 ⁶ normal spleen cells	8.1	73.2
40 × 10 ⁶ <i>C. parvum</i> spleen cells	6.1	18.3‡
20 × 10 ⁶ <i>C. parvum</i> spleen cells	7.7	30.6‡
10 × 10 ⁶ <i>C. parvum</i> spleen cells	7.8	50.7‡

*CP spleen cells were used 8 d after intraperitoneal injection of 1.4 mg into normal C57BL/6 mice. Normal spleen cells or *C. parvum* spleen cells were cocultivated with MSV 30 spleen cells for 5 d *in vitro* in the presence or absence of mitomycin C-treated RBL-5 cells and subsequently tested for their ability to lyse RBL-5 cells in a 4 h cytotoxicity assay at a 50:1 effector cell-target ratio.

†Mean % ⁵¹Cr release of quadruplicate determinations.

‡Significant (*P* < 0.05) suppression by *C. parvum* spleen cells when compared with the effect of the same number of normal spleen cells.

To investigate the nature of the suppressor cells in *C. parvum* spleens, *C. parvum* spleen cells were added to MSV 30 spleen cells after pretreatment with various techniques. These have been described in detail previously^{11,13}, and included treatment by anti-θ serum plus complement, by an iron/magnet technique, by rayon adherence columns, and by 2,500 rad X irradiation. Controls consisted of normal spleen cells treated by the same

techniques. The results of these experiments are summarised in Table 3. In four different experiments, a marked secondary cytotoxic response was seen in cultures of MSV 30 spleen cells which ranged between 64.3 and 78.4%. Addition of an equal number of normal spleen cells, either untreated or treated by any of the techniques mentioned above had little or no inhibitory effect. In contrast, *C. parvum* spleen cells consistently suppressed the cytotoxic response of MSV 30 spleen cells. Their effect was eliminated by pretreatment with the adherence columns or with the iron/magnet technique. The suppressive capacity of *C. parvum* spleen cells was not removed by pretreatment with anti-θ serum plus complement or by irradiation with 2,500 rad.

These results indicate that the cells in *C. parvum* spleens which inhibit the secondary cytotoxic response of immune spleen cells to tumour-associated antigens are radioresistant non-T cells. A role of B cells has not been definitively ruled out. The iron/magnet technique and the adherence columns as used in our laboratory, however, although effective in removing macrophages, do not selectively deplete B lymphocytes (this was shown both by stimulation with the B cell mitogen LPS and by determination of cells with detectable surface immunoglobulin). Therefore, our data suggest that the suppressor cells in *C. parvum* spleens are macrophages. This is in accord with the results of studies of the suppression of mitogen responses of normal spleen cells by *C. parvum* spleen cells⁶, in which the suppressor cells within *C. parvum* also appeared to be macrophages. In other studies, activated macrophages have been demonstrated after injection of *C. parvum* which inhibited the *in vitro* proliferation of tumour cells^{6,14}. Subsequently, we have presented evidence that in spleens of *C. parvum*-injected mice the same cells may suppress mitogen reactivity and inhibit tumour cell proliferation *in vitro* (H.K. *et al.*, unpublished). It is conceivable that activated macrophages have the same dual effect *in vivo* after injection of *C. parvum*. There may be a balance between immunosuppression and the inhibition of tumour cell growth, and it is possible that treatment schedules with the greatest activation could result predominantly in immunosuppression and consequent facilitation of tumour growth. Indeed, in one experimental tumour system, strong tumour protection occurred in conditions of minimal systemic activation, whereas there was little protection after systemic administration of *C. parvum*⁶. This lack of protection may be caused by similar suppressor cells as described here. Furthermore, it has been observed that tumour protection by injection of X-irradiated tumour cells has been diminished in mice pretreated with *C. parvum*⁵.

In conclusion, our data show the depression of anti-tumour cellular immunity by treatment with *C. parvum*. These data are not necessarily at variance with reports in which a tumour-protective effect of *C. parvum* has been shown. *C. parvum* may

turn out to be a useful therapeutic agent in the treatment of cancer. Our data suggest, however, that there may be quite a delicate balance between the beneficial anti-tumour effects of *C. parvum* and its immuno suppressive effects. Considerable experimentation seems to be necessary to determine the various factors contributing to this complex situation. Therefore, caution should be exercised in using *C. parvum* for immuno-therapy of human cancer.

Role of amino acids in osmoregulation of non-halophilic bacteria

MOST microorganisms show optimal growth at low osmotic pressures, but even so are often able to grow, though more slowly, in the presence of concentrations of environmental solutes sufficiently high to reduce the water activity to values as low as 0.86 (Table 1). The ability of osmophilic yeasts to grow at low water activities depends on the accumulation of high concentrations of polyhydric alcohols inside the cell¹, and similarly, halophilic bacteria accumulate potassium ions². Amino acids, especially proline, have been shown to stimulate growth³ and respiration⁴ of some bacteria at low water activities, and to accumulate in response to increased environmental sodium chloride⁵ and, more particularly, to osmotic dehydration (my unpublished results). I now report that growth of non-halophilic bacteria at low water activities seems to depend on the ability of the cell to balance the environmental osmotic pressure by intracellular accumulation of amino acids, and on the types of amino acid which accumulate.

Non-halophilic bacteria differ greatly in their tolerance to sodium chloride in the growth medium (Table 1, first and second columns). There are two possible explanations: (1) the cells are permeable to the solute and differences in tolerance reflect the intrinsic solute resistance of intracellular enzymes; (2) the cells are impermeable to the solute and must therefore compensate internally for the increased environmental osmotic pressure. To test the first possibility, the salt sensitivities of the enzymes, aldolase, isocitrate dehydrogenase and phosphohexose isomerase, were assayed in whole cell homogenates of bacteria with widely different salt tolerances (Table 2). Although differences were evident between species, these were not sufficient to explain the differences in halotolerance and, further, concentrations of sodium chloride which would totally inhibit all these enzymes *in vitro* still permitted growth of the intact cells of the three species tested. Complete permeation of solute into the cell therefore does not occur and a concentration

difference is maintained across the cytoplasmic membrane. Such a concentration difference between the inside and the outside of the cell would cause osmotically induced dehydration unless accumulation of some other osmotically active molecule occurred within the cell. An osmotically induced accumulation of proline in *Bacillus subtilis* had already been demonstrated (my unpublished results), and therefore analyses were made of the free amino acids within the cells of other species of bacteria which had been grown in the presence of high concentrations of sodium chloride. A concentration was chosen for each species which caused a 50% reduction in growth rate.

In each of the species tested, salt induced a characteristic increase in the levels of particular pool amino acids (Table 1, third and fourth columns). To balance 1 M NaCl outside the cell requires an internal concentration of approximately 1 M ionic, or 1.8 M non-ionic solute. In some instances the increase in intracellular amino acid concentration appeared insufficient to balance the external osmotic pressure (Table 1, fourth column). The probable explanation is, first, that bacteria are normally hypertonic with respect to the environment. (In fact the more osmotolerant a microorganism is, the greater is its hypertonicity, and more specifically its internal K⁺ concentration, when growing at high water activity⁶.) Consequently, a part of the added solute pressure need not be balanced by additional intracellular solute. Second, because glutamate is charged at neutral pH values, it is accompanied by a cation (usually K⁺), which also contributes to the osmotic balance. Third, and particularly for *Staphylococcus aureus*, Na⁺ may be imperfectly excluded and therefore contribute to the balance also.

That the changes in amino acid level are osmotically induced can be judged by the fact that the same qualitative changes are induced by sucrose in place of salt in the environment, but the increase of intracellular amino acid per mol of sucrose is roughly 45-50% of the increase per mol of sodium chloride.

What can induce these changes? They occur in a rich medium, when the cells transport amino acids from the medium, or in a minimal medium when they synthesise them *de novo*. Those organisms which accumulate glutamic acid in response to osmotic stress are mainly Gram-negative species which, under normal conditions, have low total amino acid pools composed almost entirely of glutamate and also low K⁺ levels. At the other extreme, those organisms which accumulate proline are Gram positive and have a large free amino acid pool under non-stressed conditions (of which, again, a large proportion is glutamate) and also a high internal K⁺ level. In fact, such Gram-positive organisms growing in the absence of osmotic stress have pools similar to those of Gram-negative organisms grown in the presence of, say, sodium chloride. It thus seems that, during osmotic stress, the fundamental reaction is an increase in pool glutamate. Among Gram-negative organisms there is scope for this increase, but among the Gram-positive organisms glutamate may already be at a limiting concentration. Accumulation of glutamic acid requires the cell to accumulate an accompanying cation in order to retain electrical neutrality. In most cases this is K⁺. The disadvantages of K⁺ accumulation to most species are the same as those of allowing NaCl to enter the cell—the inhibition of enzymatic processes. Gram-positive organisms have therefore evolved mechanisms to convert glutamate through two closely related pathways of metabolism to form the other osmoregulatory solutes, proline or γ -aminobutyric acid (GABA). Significantly, neither of these is highly charged at neutral pH value, and so will not require the presence of a neutralising cation.

Accumulation of K⁺ may also be involved in osmoregulation. The first effect of an osmotic stress is to remove water from the cell and thereby increase the intracellular K⁺ concentration. The enzyme involved in glutamate synthesis

* Microorganisms were grown with aeration at 37 °C in potato extract–yeast extract–glucose broth (Difco) with the following exceptions: *Vibrio parahaemolyticus* was grown in heart infusion broth (Difco); *Lactobacillus plantarum* in MRS broth (Oxoid); *Clostridium sporogenes* in reinforced clostridial medium (Oxoid) without aeration. Sodium chloride at various concentrations, as a solid, was added to exponentially growing cultures of the organisms and growth rate was determined by following absorbance at 580 nm. Minimum water activity for growth was then determined by extrapolating a graph of growth rate against sodium chloride concentration to zero growth rate. The water activity of this NaCl-containing medium was determined on a Sina equihygroscope.

† Microorganisms were grown at 37 °C in media containing sufficient sodium chloride to reduce the growth rate by 50%. At a concentration of 2×10^8 cells per ml cultures were collected by centrifugation and washed twice in 0.1 M phosphate buffer, pH 7.0, containing sodium chloride at a concentration the same as that in the growth medium. The cells were finally resuspended at a density of approximately 10^{10} per ml in ice-cold 5% (w/v) trichloroacetic acid. Amino acid analyses were carried out using a Technicon automatic amino acid analyser. For each species controls were grown to the same cell concentration in the absence of sodium chloride, then treated as above.

‡ Intracellular concentrations of amino acids are based on phosphate-impermeable volumes for each species.

in most bacteria in cultures not limited by ammonia is glutamate dehydrogenase, which catalyses the oxidative deamination of glutamate and (or) the reductive amination of α -ketoglutarate. Table 3 shows that this enzyme is activated by 500 mM K^+ up to tenfold in the direction of glutamate, but not at all in the reverse reaction in the several species tested. There is thus a cyclic build up of glutamate resulting from the osmotically effected increase in K^+ concentration leading to glutamate synthesis, which then requires inflow of cations to balance the charge, which further activate the enzyme. In organisms that accumulate glutamate, a concomitant increase in intracellular K^+ concentration is observed, and this is of the same magnitude as the increase in glutamate concentration. For example, in *Klebsiella aerogenes* grown in the absence of osmotic stress the intracellular K^+ concentration is 125 mM. During

growth in the presence of 1 M NaCl this increases to 625 mM, an increase of 500 mM. The extra glutamate accumulated under these conditions is 750 mM. Similar changes can be observed in other organisms.

In some bacteria, notably some *Bacillus* spp., glutamate synthesis occurs partly (or completely in the case of *Bacillus megaterium*) by a separate route, through glutamine synthetase (GS) and glutamine: α -ketoglutarate amidotransferase (GOGAT). The GS–GOGAT system is not activated by ions (Table 4), nor does the total enzyme level increase substantially during growth at low water activity and therefore other mechanisms must be involved. Ions may, for example, influence the enzymes of proline synthesis or inhibit feedback inhibition which normally limits the free proline pool level: and in some microorganisms the rate of transport of amino acids into the cell can be con-

Table 2 Inhibition of various microbial functions by sodium chloride

trolled by the internal potassium ion concentration⁸. In all cases where GS-GOGAT substantially contributes to glutamate synthesis, however, the change in amino acid pool during growth at low water activity is not principally in glutamic acid. The accumulation of proline does not require the accumulation of a neutralising cation. In those organisms which do accumulate proline, no change in K⁺ concentration can be observed during growth under osmotic stress. For example in *Bacillus subtilis* the intracellular K⁺ concentration is 250 mM irrespective of the external NaCl concentration. This does not, however, mean that any osmoregulatory mechanism cannot involve K⁺. After an osmotic shock, and before the subsequent accumulation of amino acid, water is removed from the cell by the osmotic pressure difference. Because the cell is largely impermeable to many intracellular solutes, such solutes will remain inside the cell after osmotic shock, and their effective concentrations will increase. K⁺, of course, is among these solutes. Once amino acid concentration has begun to increase within the cell, water is drawn back into the cell also, and the effective concentration of the other intracellular solutes will decrease again.

Similar osmoregulatory mechanisms to those described above operate in aquatic invertebrates⁹. Further, proline accumulation is important in plants that have evolved to resist dehydration¹⁰. Until the evolution of homoeosmotic mechanisms in higher animals this primitive mechanism may have been widespread throughout the biological world from the simplest prokaryotes through to higher plants and invertebrate animals.

I thank Professor G. W. Gould for helpful discussions and for reading the manuscript.

Heterologous reattachment of regular arrays of glycoproteins on bacterial surfaces

REGULAR arrays of macromolecular subunits have been observed on the surfaces of a wide range of bacteria in electron micrographs of negatively stained or freeze-etched preparations^{1,2}. The regular patterns have mostly tetragonal or hexagonal symmetry and the centre-to-centre spacing between adjacent subunits varies from 6 to 15 nm. Chemical analyses of isolated subunits have shown that they are composed mainly of protein¹ or glycoprotein (unpublished) with molecular weights ranging from 65,000 to 150,000. Studies of a few bacteria have shown that the isolated subunits can assemble spontaneously to form regular arrays with the same dimensions as those seen in intact bacteria³. In appropriate conditions the subunits also reattach to the surfaces of cell walls from which they have been detached. Little is known about the biological function of these regular arrays of macromolecules on bacterial surfaces. That they cover the surface, leaving no gaps², suggests that they are important, for instance, in providing protection against adverse environmental conditions. Otherwise they would be expected to have been lost during evolution.

I have examined the ability of isolated subunits to reattach to cell surfaces to understand more fully the mechanisms involved in the development and maintenance of a two-dimensional array of macromolecules on a growing cell surface, and to obtain evidence for the suggestion that the assembly of these arrays is a dynamic process². Two strains of taxonomically closely related hyperthermophilic clostridia were used (grown at 65-70 °C), *Clostridium thermosaccharolyticum* and *C. thermohydrosulfuricum*⁴, which have tetragonal and hexagonal surface patterns, respectively (Fig. 1). Various treatments were used to remove the subunits from the surface of isolated cell walls and complete removal was only obtained with H-bond dis-

Fig. 1 Electron micrographs of freeze-etched preparations of the intact cells showing a portion of *a*, the regular tetragonal arrays of subunits on the surface of *C. thermosaccharolyticum* and *b*, the hexagonal arrays on *C. thermohydrosulfuricum*. ($\times 240,000$.) Electron micrographs of preparations of cell walls from *c*, *C. thermosaccharolyticum* and *d*, *C. thermohydrosulfuricum* negatively-stained with uranyl acetate. Cells were disrupted in an Aminco French pressure cell, and clean cell walls were isolated by treatment with Triton X-100 to remove the plasma membranes and washing in Tris-HCl (50 mM, pH 7.4) buffer. ($\times 240,000$.)

rupting agents, such as urea (8 M) and guanidine hydrochloride (GHCl, 5M). EDTA, Triton X-100, dithiothreitol and proteolytic enzymes, such as papain, trypsin, Pronase and thermolysin, had no visible effect on surface patterns. Analysis of treated cell walls and urea and GHCl extracts by sodium dodecyl sulphate (SDS)-polyacrylamide electrophoresis showed that the subunits of the surface layer form a major band which stains for both protein and polysaccharide (U.B.S., and K. J. I. Thorne, unpublished). The subunit protein of both microorganisms has a predominantly acidic amino acid composition and an acidic isoelectric point after isoelectric focusing on polyacrylamide gels. The molecular weights were 140,000, as determined by SDS-polyacrylamide electrophoresis.

Acidic conditions had an unexpected effect on the surface pattern. When cell walls were treated with buffer at a pH lower than 3, the regular arrays of subunits were no longer visible in negatively stained or freeze-etched preparations, and no periodicity was detectable in optical diffraction analyses of electron micrographs. No protein was lost, however, and the regular patterns reappeared very clearly when the pH was adjusted to neutral. Consequently it was con-

cluded that acidic conditions cause an uncoiling of the surface glycoprotein but do not detach it from the cell surface. When urea or GHCl extracts were dialysed against buffer at neutral pH (Tris-HCl, 50 mM, pH 7.4) the isolated subunits of both organisms could assemble into regular arrays *in vitro* in the absence of any supporting layer. This process was reversible, and the self-assemblies could be disintegrated and reformed by lowering and raising the pH, down to 2-3 and up again to 7. High salt concentrations (3 M KCl) had no effect on the self-assemblies. These chemical studies show that covalent bonds are not involved in the linkage between the subunits in the regular array, or between the subunits and the surface layer of the cell wall.

Isolated subunits reattach to cell walls in various conditions, such as dialysis of a mixture of urea or GHCl extract with 'naked' cell walls against distilled water or buffer. The reattached subunits form small areas of regular pattern, or crystallites, at various orientations (Fig. 2), and not the large regular arrays observed on intact cells. An unexpected finding was that subunits from one organism can attach to cell walls of the other organism and form patterns identical to those on the cells from which they originated. In addition, when cell walls from one organism are incubated with a mixture of both types of subunit, regular arrays, some with hexagonal and some with tetragonal symmetry, were observed on individual cell walls (Fig. 3). The two patterns were observed with equal frequency and the cell walls did not seem to favour the attachment of one type of subunit over the other. These observa-

Fig. 2 Negatively stained preparation of a fragment of cell wall from *C. thermohydrosulfuricum* which was incubated with subunits isolated from the same organism. The reattached subunits form small areas of hexagonal pattern. ($\times 120,000$.)

Fig. 3 Negatively stained preparation of a fragment of cell wall from *C. thermosaccharolyticum* which was incubated with a mixture of both types of isolated subunit. Small arrays of both hexagonal and tetragonal patterns are visible. ($\times 180,000$.)

tions clearly demonstrate that the information for the formation of the regular patterns resides in the subunits themselves, and is not affected by the supporting cell wall layer. In addition, the crystallites are orientated at random on the cell walls, suggesting that their orientation is not determined by any pattern in the binding sites in the cell wall.

An analysis of freeze-etched preparations of regular arrays of subunits on logarithmically growing cells of both clostridia, and other studies on thin sections (unpublished), have shown that large numbers of newly formed subunits appear at sites of division. These subunits first form a mosaic of small crystallites and subsequently rearrange themselves into large areas of uniform pattern during cell separation. From these observations it was concluded that the subunits undergo a dynamic process of assembly during cell growth². Such a process also requires a non-orientating supporting layer which allows free rotation and movement of subunits into the regular pattern. Thus it seems that the pattern is only determined by the directional bonds between the subunits and presumably represents the arrangement in which there is least strain and minimum energy in these bonds. The ability of the subunits to self-assemble into regular arrays and to adhere readily to the cell surface provides a simple mechanism for keeping a growing surface completely covered with a monolayer of macromolecules, providing that an excess of subunits is available either inside or outside the cell. The alternative mechanism of growth of a surface layer composed of regular arrays of macromolecules by the migration of dislocations⁹ is much more complex since it requires both the precise incorporation of subunits at particular points on the surface and that the rate

of glycoprotein synthesis be synchronised with the rate of synthesis of the underlying cell wall.

Existence of a follicle-stimulating hormone inhibiting factor 'inhibin' in bull seminal plasma

THE existence of a substance of testicular origin capable of inhibiting the secretion of pituitary follicle-stimulating hormone (FSH) was postulated by McCullagh¹, who gave it the name 'inhibin', and direct, though not conclusive, evidence for its presence has since been provided²⁻⁶. After extraction and gel chromatography of bull seminal plasma, Franchimont *et al.*^{7,8} obtained a proteinaceous fraction (AcII) capable of decreasing basal FSH levels as well as diminishing the FSH response to exogenous luteinising hormone releasing hormone (LHRH) in normal and castrated adult male rats. We here summarise work based primarily on the specific biological effects of antiserum to AcII in rats, suggesting the existence of inhibin in bull seminal plasma.

Gel chromatography of bull semen (see Table 1) yielded a major unretarded peak (AcI: 200 ± 10 mg) followed by another distinct peak (AcII: 45 ± 5 mg) with a trailing edge. When 200- μ g aliquots of AcII were analysed by polyacrylamide gel electrophoresis⁹ (pH 8.6; gel concentration 10%), it was resolved into at least three components, as revealed by staining with Amido black.

AcI caused no significant decrease in serum FSH or LH in castrated adult male rats at a dose of 500 μ g per animal^{7,8}, whereas 200 μ g of AcII, intraperitoneally or intravenously, caused a consistent and significant decrease in serum FSH without affecting LH (Table 1). With normal intact males, a dose-dependent decrease in FSH was obtained after intraperitoneal injection (experiment 1, Table 1), although pituitary weight and gonadotrophin content were not affected.

The active fraction was examined for the possible presence of specific androgen binding protein (ABP) with high affinity for testosterone and dihydrotestosterone (DHT)¹⁰. Samples (100 and 200 μ g) were equilibrated at 0 °C for 2 h with tritiated testosterone, DHT and 17- β -oestradiol¹⁰. Proteins were fractionated by polyacrylamide gel electrophoresis and the radioactivity measured in 2.5-mm thick slices of the gel¹¹. No steroid-binding capacity for testosterone, DHT or 17- β -oestradiol could be detected in any of the three components of AcII. Thus, inhibin is neither identical nor similar to ABP elaborated by Sertoli cells under the influence of FSH¹⁰. The possibility that the biological effect of the active material was caused by contamination with steroids or their conjugates, was excluded by radioimmunoassay for testosterone, progesterone and 17- β -oestradiol after appropriate organic solvent extraction¹². None of these steroids

Male albino Wistar rats (180–200 g) were given the total dose as four intraperitoneal (i.p.) injections at 12-h intervals. Rats were killed 4 h after the last injection, and blood and pituitaries collected. Alternatively, the test material or saline was administered as a single dose intravenously (i.v.) by way of the tail vein. Animals were autopsied 1 h later. Castrated animals were used 15 d after surgery. Serum samples were assayed for FSH and LH by radioimmunoassay using NIAMD systems¹⁸. Freshly collected bull semen was centrifuged at 4 °C to remove spermatozoa, and protein from the supernatant precipitated by addition of alcohol to a concentration of 86% (v/v). The precipitate was recovered by centrifugation in the cold, dissolved in distilled water and lyophilised. Batches of 300 mg were subjected to gel chromatography on Sephadex G100 in columns with a packed dimension of 2.5 × 30 cm, using 0.05 M acetate buffer pH 4.0 for equilibration as well as elution.

**P* < 0.05; †*P* < 0.025.

was detected in as much as 1,200 µg AcII. The possibility that the observed action of AcII may be a result of the presence of gonadotrophins, their fragments or metabolites, was also excluded by the fact that AcII does not cross react with either FSH or LH from man, sheep, rabbit or rat in the corresponding radioimmunoassay^{13–16}. An antiserum raised against AcII (see below) failed to bind labelled gonadotrophins of different species.

What seems to be significant is the demonstration that antibodies to inhibin can be raised in rabbits by active immunisation (2 mg AcII per animal in 1 ml saline mixed with an equal volume of Freund's complete adjuvant injected intradermally at several sites, followed by four booster intramuscular injections at 10–12-d intervals of 1 mg per animal in Freund's complete adjuvant; 15 d after the last injection the animals were bled by way of the carotid artery and sera recovered). The antiserum thus obtained is able to induce a marked increase in plasma FSH when injected into male or female rats.

The antiserum provoked a significant increase in the serum FSH levels in intact adult male rats when injected subcutaneously once a day for 4 d at doses of 0.5, 0.8 and 1.0 ml per animal, whereas serum LH, blood testosterone and testis and accessory organ weights were not significantly increased (Table 2). Nor did the antiserum lead to any histological changes in the seminiferous tubules.

In adult female rats, a dose of 1 ml antiserum per animal

Table 2 Effect of antiserum to seminal plasma fraction AcII on adult male rats

Treatment	No. of rats	Serum FSH (ng ml ⁻¹ ± s.e.m.) NIAMD-FSH-RP ₁	Serum LH (ng ml ⁻¹ ± s.e.m.) NIAMD-LH-RP ₁
Normal rabbit serum	25	320.7 ± 85.05	104 ± 69.5
0.2 ml Anti-AcII serum	5	306.0 ± 51.7	156 ± 76.3
0.4 ml	5	332.0 ± 66.4	121 ± 47.3
0.5 ml	5	958.8 ± 144.2*	209 ± 105.5

Table 3 Effect of antiserum to seminal plasma fraction AcII on adult and immature female rats

Treatment	No. of rats	Serum FSH- (ng ml ⁻¹ ± s.e.m.) NIAMD-FSH-RP ₁	Serum LH (ng ml ⁻¹ ± s.e.m.) NIAMD-LH-RP ₁
Adult rats			
Normal rabbit serum	5	203 ± 44.8	86.3 ± 34
Anti-AcII serum 1 ml per rat	5	3,120 ± 261.9†	715 ± 49.9*
Immature rats			
Normal rabbit serum, 0.5 ml per rat	6	330 ± 44.1	135.8 ± 33.1
Anti-AcII serum, 0.5 ml per rat	6	8,900 ± 517.9†	1,808 ± 291*

Adult (180–200 g) and immature (21–24-d-old) female Wistar rats were treated with a total dose of 1.0 or 0.5 ml antiserum to AcII according to the schedule described in Table 2. Pituitary and serum gonadotrophin and serum 17-β-oestradiol were measured by radioimmunoassay.

**P* < 0.005; †*P* < 0.001.

significantly elevated both FSH and LH levels without affecting serum 17-β-oestradiol, ovarian or uterine weights (Table 3). Administration of antiserum to immature female rats resulted in an even more pronounced elevation of both FSH and LH (Table 3). The antiserum had no effect on the pituitary gonadotrophin content in male or female rats. The FSH response to 1 ml antiserum was more striking in the adult female (1,536% control) than in the adult male (443% control), which could be a reflection of the different sensitivities of the male and female hypothalamo-hypophysial axis to inhibin. The apparent FSH specificity of responses to antiserum in male animals may be dose dependent: higher doses may also stimulate LH release in much the same way as small doses of LHRH selectively increase LH, whereas increasing doses stimulate the release of both FSH and LH in adult human subjects¹⁷.

Our observations, particularly those relating to the effect of antiserum to AcII, clearly demonstrate the existence in bull seminal plasma of a proteinaceous substance capable of diminishing circulating levels of gonadotrophins, especially FSH, in male and female rats. This substance, which corresponds with the definition of inhibin, may be important not only in the control of spermatogenesis but also of the oestrous cycle. In the light of the effects of the antiserum to AcII in immature females, the possibility

exists that this substance may also be important for the transition of females from sexual immaturity to adulthood.

Observations on the differential effects of normal and azoospermic human seminal plasma on FSH levels in adult, castrated rats² clearly implicate the germinal epithelium as the source of inhibin. Setchell and Sirinathsinghji³ pointed out that the logical route out of the testis for such a substance would be by way of the rete testis fluid (RTF) and the epididymis. Although a substantial part may be reabsorbed, together with RTF in the head of the epididymis, it would not be unusual to find this substance in the ejaculate. Viewed in this light, it is tempting to speculate that the source of inhibin in bull seminal plasma is indeed the germinal epithelium of the testis; however, we do not as yet have any evidence bearing directly on this possibility.

Brain lesions and precocious puberty in rats

IN the immature female rat, the ability to secrete the gonadotrophins luteinising hormone (LH) and follicle-stimulating hormone (FSH) in response to a single injection of oestradiol or of progesterone first appears about day 28 of life^{1,2}. Younger animals respond to these hormonal stimuli with an increased release of gonadotrophins only if they have been primed with an injection of oestrogen 3 or more days earlier, and it is assumed that the priming steroid promotes the functional maturation of a positive (stimulatory) feedback system³ by an unknown mechanism. Alternatively, electrolytic lesions in the area of the basal hypothalamus of 23-d-old rats induce precocious sexual maturation leading to pubertal ovulation within 4 or 5 d (ref. 4). The lesion site is rich in luteinising hormone releasing hormone⁵, and it seems likely that the discharge of this polypeptide triggers the rapid and sustained increase in the production of ovarian steroids, particularly of oestrogen, observed during this period⁴. We report here that the increase of endogenous steroid in response to a brain stimulus can prime the positive feedback system in a manner closely related to the effect of exogenous oestrogen. This suggests that brain lesions advance the process of sexual maturation through the precocious establishment of a positive feedback loop.

Female Sprague-Dawley rats were kept on a 12/12 h light/dark cycle (lights on at 0700). On day 23 of life, at about noon, animals weighing > 56 g either received an injection of 10 µg oestradiol benzoate (OB) in oil (0.2 ml, subcutaneously) or

Fig. 1 Plasma LH and FSH concentrations 5 h after an injection of progesterone (P) in rats primed with oestradiol benzoate (OB) or with a brain lesion (L) and in controls. Samples were run in duplicate. Results are expressed as mean \pm s.e. in terms of NIAMDD-rat LH-RP-1 and FSH-RP-1 reference preparations. Control values of LH falling below the detection limit of the assay were considered to be 15 ng ml⁻¹. C, untreated controls. Indices refer to age (in d) at which treatment was applied.

were subjected to a small unilateral electrolytic brain lesion placed stereotactically near the origin of the pituitary stalk⁴. Seventy-two hours later the rats received 1 mg of progesterone in oil (0.2 ml, subcutaneously); they were decapitated 5 h later (that is at 1700 on day 26). Plasma was assayed for LH and FSH concentrations using NIH radioimmunoassay kits. Controls were either untreated littermates of similar body weight, were subjected to brain lesions alone or were injected with progesterone only on day 26.

Figure 1 illustrates that both types of sequential treatment elevated mean plasma LH concentrations more than 20-fold compared with all types of controls ($P < 0.005$; Student's *t* test). FSH concentrations were significantly ($P < 0.05$) higher

Table 1 Degree of uterine hypertrophy induced by oestrogen/progesterone treatment or by sequence brain lesion/progesterone compared with controls

Group	n	Treatment	Uterine weights (mg; mean \pm s.e.)	Significance (two-tailed <i>t</i> test)
1	8	OB ₂₃ /P ₂₆	150.9 \pm 5.9	1 against 2, $P > 0.2$
2	8	L ₂₃ /P ₂₆	140.0 \pm 12.6	
3	8	L ₂₃ only	104.5 \pm 14.6	3 against 4, $P > 0.2$
4	8	OB ₂₃ only	121.3 \pm 3.6	
5	8	P ₂₆ only	32.1 \pm 1.9	
6	8	None	36.7 \pm 5.5	

n, Number of animals per group. Rats were killed at 1700 on day 26, and uteri were dissected on filter paper. Indices as in Fig. 1.

after the combined hormonal treatment than after the sequence brain lesion/progesterone, but plasma values found after the latter approach nevertheless significantly ($P < 0.05$) exceeded control values in all groups. LH and FSH concentrations in controls were low, indicating that neither the brain lesion as such nor the injection of progesterone into unprimed animals can markedly increase plasma concentrations at this time.

The effect of the two treatments on uterine growth was compared (Table 1). The brain lesion (group 2) was found to substitute fully for the priming injection of OB (group 1) in this scheme; likewise, the degree of uterine hypertrophy induced by the lesion alone (group 3) was not significantly less than that seen after an injection of OB alone (group 4). In contrast, no uterine growth was induced when progesterone only was given on day 26 (group 5). From this cumulative bioassay, it is concluded that the brain lesion is equivalent to approximately 10 µg of injected OB.

The mode of action of brain lesions in the induction of precocious puberty is obscure⁶. It has been suggested that lesions eliminate the neural substrate which mediates the inhibitory action of gonadal steroids on the reproductive axis⁷. However, small unilateral lesions which spare most demonstrated oestrogen⁸ and progesterone⁹ uptake sites are efficient inducers of puberty⁴. Precocious sexual maturation can also be triggered, in rats, by repeated administration of oestrogen¹⁰ or by a single injection of pregnant mare serum gonadotrophin, and, in mice, by male-produced pheromones. The latter two mechanisms are dependent on the secretion of endogenous oestrogen^{11,12}. We submit that oestrogen also reinforces the stimulatory effect of the hypothalamic lesion.

This work was supported by a grant from the Swiss National Science Foundation and a subsidy from the Société Académique de Genève. We thank Miss D. Cassard for technical assistance. Rat LH and FSH immunoassay materials were provided by the NIAMDD-NIH rat hormone distribution programme.

Rapid and dissociated changes in sensitivities of different dopamine receptors in mouse brain

DOPAMINERGIC systems in various parts of the mammalian brain, particularly in striatal, mesolimbic, mesocortical and hypothalamic structures, are involved in the control of motor activity, autonomic processes and emotional behaviour. An altered dopaminergic transmission in striatum seems to be responsible for Parkinsonism, whereas abnormalities in other, still poorly defined, dopaminergic synapses could participate in the aetiology of schizophrenia¹⁻³. Thus, there is considerable theoretical as well as therapeutical

interest in defining specific characteristics of different dopaminergic systems participating in the control of these various functions.

Hypersensitivity to the action of specific dopamine agonists like apomorphine has been observed after either denervation⁴ or long term treatment with agents interrupting dopaminergic transmission⁵⁻⁷, whereas desensitisation occurs after chronic stimulation⁸. The study of these states of modified receptor sensitivity may contribute to the understanding of the various factors controlling dopaminergic transmission in normal and pathological conditions and may also be helpful in defining several classes of dopaminergic synapses.

We observed that the sensitivity of dopamine receptors involved in thermoregulation and in a particular motor behaviour can be rapidly altered after a single administration of moderate dosage of an agonist (apomorphine) or an antagonist (haloperidol), respectively; however, whereas dopamine receptors controlling thermoregulation are easily desensitised and do not develop supersensitivity, the reverse is true for those implicated in the motor behaviour.

Male Swiss albino mice (22-26 g, Charles River, Saint Aubin-lès-Elbeuf, France) were housed in a well ventilated room, at 24 °C and under artificial illumination (light on between 0800 and 2000). Three hours before the experiments the animals were housed without food in small individual cages at 22 ± 1 °C. Body temperature was measured with a thermoelectric probe (Ellab RM 6, Copenhagen) inserted 4 cm into the rectum, immediately before and at various intervals after subcutaneous injection of apomorphine. Apomorphine induced an hypothermia which was related to dose both in intensity and in duration. The maximal hypothermia in controls (saline-pretreated mice) was observed at about 5 mg kg⁻¹ of apomorphine (Fig. 1) and lasted for about 90 min. In mice pretreated with this dose and tested after 8 h, there was a significant shift to the right of the dose-response curve: although the maximal hypothermia (-3 °C) was not modified, the ED₅₀ for apomorphine was 2.80 ± 0.59 mg kg⁻¹ as compared with 0.35 ± 0.06 in controls (calculated by the method of Miller and Tainter⁹). On the other hand, the hypothermia induced by agents, such as oxotremorine (0.05 mg kg⁻¹), clonidine

Fig. 1 Modification in the apomorphine-induced hypothermia after a single administration of the drug. Dose-response curves were established 8 h after the subcutaneous injection of either apomorphine (5 mg kg⁻¹) or saline. The effects of test doses of apomorphine were recorded 30 min after subcutaneous injection. Means ± s.e.m. of 10-15 experiments for each dose. Means were compared by Student's *t* test. * $P < 0.05$; † $P < 0.01$; ‡ $P < 0.001$.

(0.25 mg kg⁻¹) or promethazine (10 mg kg⁻¹), acting on other systems, was not modified in the apomorphine-pretreated animals.

In mice treated with an antagonist of dopamine receptors, the antipsychotic drug haloperidol (0.1 mg kg⁻¹, intraperitoneally), the hypothermic action of apomorphine (0.45 mg kg⁻¹) was blocked for at least 10 h. After 72 h, the dose-response curve to apomorphine of mice pretreated with haloperidol (either 0.1 or 4 mg kg⁻¹) was not significantly different from that of controls. Similarly, the responsiveness to a single dose of apomorphine (0.30 mg kg⁻¹) was not altered 4, 5, 7 and 10 d after haloperidol (4 mg kg⁻¹).

In addition, a peculiar motor behaviour, that is climbing or verticalisation induced by apomorphine (refs 7, 10, 11 and P.P., J.C. and J.C.S., unpublished) was evaluated. For that purpose, after drug administration, the mice were immediately put into individual cylindrical cages, 12 cm diameter, 14 cm high, with walls of vertical metal bars, 2 mm diameter, 1 cm apart, surmounted by a smooth surface. After a 5-min period of exploratory behaviour, whereas the controls remained on the floor of the cage, the apomorphine-treated mice tended to adopt a vertical position holding the bars for at least 30 min, either with their forefeet only (small doses of apomorphine) or with all four paws (larger doses). This behaviour was scored as follows: four paws on the floor (0), forefeet holding the wall (1), four paws holding the wall (2). Two observations were performed on each animal, 10 and 20 min after injection of apomorphine and the two scores averaged. In controls, the maximal score was obtained for about 1.0 mg kg⁻¹ of apomorphine with an ED₅₀ of 0.50 ± 0.04 mg kg⁻¹ (Fig. 2). In mice pretreated with haloperidol (4 mg kg⁻¹, intraperitoneally) 72 h earlier, the dose-response curve to apomorphine was shifted significantly to the left (ED₅₀ = 0.27 ± 0.02 mg kg⁻¹).

Although pretreatment with apomorphine resulted in a diminished sensitivity to its hypothermic effect, the same was not true for the climbing behaviour. In fact, 8 h after administration of apomorphine (5 mg kg⁻¹) the ED₅₀ was 0.11 ± 0.02 mg kg⁻¹ as compared with 0.45 ± 0.04 for animals pretreated with saline in the same experiment. This

Fig. 2 Modification in the climbing behaviour induced by apomorphine after a single administration of haloperidol. Dose-response curves (10–30 experiments for each dose) were established 72 h after the intraperitoneal injection of either haloperidol (4 mg kg⁻¹) or saline. Means were compared by the χ^2 test ($P < 0.001$). □, Haloperidol-pretreated mice; ●, saline-pretreated controls.

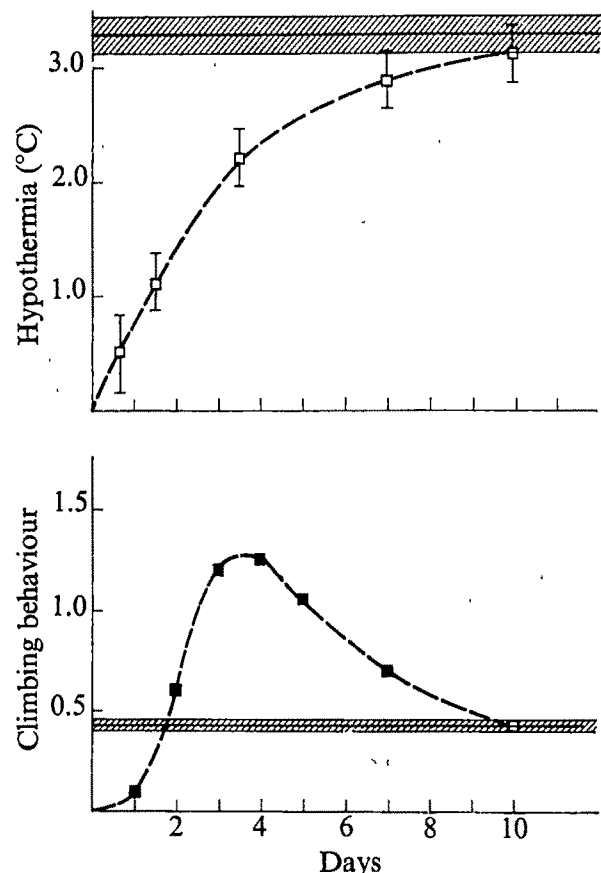

Fig. 3 Modification in the responses of mice to apomorphine at different times after a single pretreatment with either apomorphine (□, 5 mg kg⁻¹ subcutaneously) or haloperidol (■, 4 mg kg⁻¹ intraperitoneally). The intensity of the hypothermia in apomorphine-pretreated mice was determined 30 min after the subcutaneous injection of a test dose of 0.45 mg kg⁻¹ apomorphine (means of 15–30 experiments for each time interval). The climbing behaviour was scored after the subcutaneous injection of a test dose of apomorphine 0.30 mg kg⁻¹ (means of 10 experiments for each time interval). In both cases, the shaded area represents the mean ± s.e.m. of responses in saline-pretreated controls.

apparent facilitation of the climbing behaviour (which was also observed after a chronic treatment with apomorphine) could be due to the lack of hypothermia in these pretreated animals. This is suggested by a similar facilitation of the climbing behaviour, evaluated in naive animals, when they were kept at an environmental temperature of 30 °C instead of 22 °C, which compensates for the apomorphine-induced hypothermia.

Thus, it seems that a single administration of a drug acting at dopaminergic receptors is sufficient to modify the activity of apomorphine. It was therefore of interest to determine the onset and duration of the subsensitivity induced by apomorphine pretreatment and the hypersensitivity elicited by haloperidol (Fig. 3).

As early as 2 h after a dose of apomorphine (5 mg kg⁻¹, subcutaneously), when the normal temperature is reached again, a test dose of apomorphine (0.45 mg kg⁻¹) which, in controls decreased the temperature by 3 °C, had no effect. This refractoriness decayed progressively: it was still significant 4 d after treatment and completely disappeared only by 10 d. With regard to the climbing behaviour, the onset of the haloperidol-induced hypersensitivity could not be so precisely determined since the blockade by the antipsychotic lasted at least 24 h but there seemed to be no time lag between blockade and appearance of hypersensitivity (Fig. 3). Hypersensitivity was maximal between 72 and 96 h and also ceased by 10 d.

Modifications in the sensitivity of dopamine receptors

probably account for the modified responsiveness to apomorphine. The alkaloid is recognised as a specific agonist of dopamine receptors in the central nervous system on the basis of behavioural and biochemical evidence obtained in whole animal studies; in addition, the drug stimulates adenylate cyclase in striatal homogenates with a potency comparable with that of dopamine. The effects of apomorphine (including those two presently studied) are, like those of dopamine, antagonised by antipsychotics¹³.

It is unlikely that pretreatment with haloperidol or apomorphine interfered with the metabolism of the alkaloid since such a mechanism would have resulted in similar shifts in responsiveness in the two tests, which was obviously not the case. In addition, chronic pretreatment with haloperidol did not modify the apomorphine distribution in the brain⁷. It is also unlikely that the diminished hypothermic response to apomorphine resulted from a nonspecific compensatory adaptation of thermoregulatory mechanisms to the initial hypothermia since the response of other hypothermia-inducing agents like oxotremorine, clonidine, or promethazine, was not modified in apomorphine-pretreated mice. Also, subsensitivity to apomorphine developed as well when the hypothermia produced by the first treatment was prevented by keeping the mice in a hot environment.

Several studies have recently indicated that dopamine receptors in the CNS mediating various behaviours are either supersensitised by pharmacological interruption of synaptic function^{4,7} or, conversely, other receptors may be desensitised by sustained stimulation⁸. These results were, however, obtained by treatments extending over periods lasting from several days to several weeks. The striking feature in our experiments, which could bring new light to the process involved, was the rapid onset of the state of modified receptor sensitivity following the administration of a single dose of either the agonist or the antagonist. In fact in both cases there was no apparent time lag between the end of the drug effect and the appearance of this state of modified sensitivity, suggesting that the modifications take place while the drug is still acting on the receptor.

These events could be explained by postulating a conformational or functional change in the receptor as a direct result of drug combination or, more probably (as it is also observed after denervation), as an indirect consequence of the altered impulse activity in the postsynaptic neurone. The altered receptor would have either a different affinity for the agonist or a modified ability to initiate the characteristic responses: the shift in the dose-response curves, without alteration of the maximal responses (especially in the case of hypothermia which is clearly a gradual process) rather favours the first hypothesis.

It is interesting that the state of modified sensitivity had approximately the same duration in the two cases (that is, after hypersensitisation by haloperidol or desensitisation by apomorphine) which suggests that similar recovery processes are involved. The rather long duration of these states of modified sensitivity to apomorphine, which outlast by several days the drug action, may represent the time required either to replace non-reversibly modified receptors by newly-synthesised ones or, alternatively, to stabilise compensatory neuronal circuits.

The other interesting feature of the present observation is the easy desensitisation of dopamine receptors involved in thermoregulation which contrasts with their inability to exhibit hypersensitivity, although the opposite characterised those mediating the climbing behaviour, which could be hypersensitised but not desensitised. Reasons for this difference are not clear at present, but may be related to their location in different brain areas. The receptors mediating hypothermia seem to be localised in the mesolimbic system¹³ or, possibly, in the newly discovered dopaminergic system in the hypothalamus¹⁴. On the other hand, the climbing behaviour, which was suppressed by electrocoagulation

of the striatum and facilitated after denervation by 6-hydroxydopamine injected into this region (P.P., J.C. and J.C.S., unpublished), seems to be mediated by striatal receptors.

The exact relationship between the opposite changes in sensitivity and the location in different brain areas remains to be explored, however. One possible explanation could be that the first category of dopamine receptors (mediating the hypothermia) are, before any treatment, already in a state of maximal functional sensitivity whereas the reverse is true for the others, a difference which could result from the different activities in the respective presynaptic neurones. Other cerebral receptors, mediating the activation of cyclic AMP synthesis elicited by noradrenaline could be either desensitised¹⁵ or hypersensitised¹⁶.

Whatever their mechanism, the rapid, sustained and independent changes in sensitivities of different dopamine receptors in the brain may have important implications. It could provide an additional way to differentiate classes of dopaminergic synapses, a task not yet feasible by observing the short-term effects of drugs. It could be helpful in the development of animal models of diseases associated with altered dopaminergic transmission in the CNS. Finally, it could possibly offer a new therapeutic approach to these diseases.

We thank Professor J. P. Green for advice and Dr J. M. Lecomte (Laboratoire Le Brun, Paris) for kindly providing the samples of haloperidol.

Release of ATP from stimulated nerve electroplaque junctions

THREE successive phases can be distinguished when the amplitude of the electrophysiological response of *Torpedo* electroplaques is recorded during stimulation at 5 or 10 Hz (ref. 1). A decrease, lasting about 30 s, is followed by a plateau of about 30 s during which the amplitude is maintained at 30-40% of its initial value. After the plateau, a late decrease brings the response to negligible levels in a few minutes. These three phases are correlated with variations in the tissue level of total acetylcholine (ACh)—the amount of transmitter decreasing during the first phase, increasing to control levels during the plateau and declining again. These variations are about 30-40% of the total level of ACh. No change is observed when only the pool of bound ACh is measured^{2,3}. In *Torpedo* homogenates, bound ACh (protected from hydrolysis by esterases³) is associated with a population of synaptic vesicles, which have been isolated by fractionation techniques⁴. It has been shown that ATP is

Fig. 1 Electric tissue and corresponding nerve. Perfusion fluid is brought by the Pasteur pipette (p), and the drops collected in the vial (V); a thread (t) holds the tissue; the nerve (n) is stimulated by the electrodes (St), and the response recorded by recording electrodes (Rec). Recording electrodes at each end of one prism. ●, Without curare; ○, with curare. *a* and *b*, Two experiments showing that ATP was collected in the perfusate when the nerve is stimulated. *c* and *d*, Curare inhibited the release of ATP. A section of electric organ (1 or 2 prisms thick) was dissected with its corresponding nerve, the fish being anaesthetised with Tricaine (1 g per 3 l seawater). The tissue was superfused with a physiological solution as described previously. The fluid (1 drop every 10 s) was collected in vials, in which the ATP assay was immediately carried out using the firefly luciferin-luciferase method. The Sigma-buffered firefly lantern extract was dissolved in 5 ml water and 100 μ l of the solution was added to the sample containing ATP. The light emission was measured using a liquid scintillation spectrometer SL30 intertechnique.

present in the vesicular fraction⁵. When *Torpedo* electric organ tissue is stimulated more than would be necessary to exhaust the electrophysiological response, or when for some other reason synthesis of new transmitter is rendered inefficient, a decrease in bound or vesicular ACh is observed. Of all the variations in ACh described, only the decline in bound ACh has been thoroughly investigated and confirmed by other laboratories⁶. It is known from fractionation experiments that both ATP and ACh are associated with synaptic vesicles, and a decrease in the vesicular content of the two substances was found in the experimental conditions that produce a decline in the pool of bound ACh (ref. 6). Several authors have collected ATP in the perfusate from stimulated neuromuscular junctions⁷⁻⁹, but the nucleotide was not found in perfusates from stimulated autonomic ganglia¹⁰.

As the electric organ of *Torpedo* is richly innervated and homologous to neuromuscular junctions, the preparation may be used to determine whether or not the nucleotide is

released, and if so from what structure such release occurs (for details of method, see Fig. 1).

Figure 1 shows that some ATP is released when the tissue is mounted, but this rapidly decreases to background levels. The stimulation (pulses of 1 ms duration at 5 Hz) was delivered to the nerve. A maximal initial response of 6–8 V was recorded and its decline followed during a 10-min stimulation period. Immediately after the onset of stimulation, ATP appears in the superfusate and its level falls when the electrophysiological response is exhausted. (Fig. 1*a* and *b*). In a similar experiment, carried out after incubating the tissue for 30–60 min in *d*-tubocurarine chloride 10^{-4} M, the electrophysiological response was reduced to a few 100 mV and the amount of ATP released on stimulation became negligible (Fig. 1*c* and *d*). In similar experimental conditions using labelled precursors of ACh, we have shown that the release of transmitter was not affected by curare. If we assume that the only effect of curare is to protect the post-synaptic cell from the effects of ACh, these results suggest that ATP release during stimulation is a postsynaptic event. In previous work, it has also been shown that the tissue level of ATP declines during stimulation and that this effect is inhibited by curare¹¹.

Such ATP release may be considered as a postsynaptic event probably independent of the decrease in vesicular ATP occurring when the bound pool is utilised. We have also observed^{12,13} in-phase oscillations in the levels of ACh and ATP during stimulation. These fast oscillations (5-s period) are still not fully understood and may not necessarily be connected with the release of ACh from the nerve terminal or with postsynaptic ATP release. Moreover, it has previously been observed that addition of ATP to the incubation bath modifies the evolution of the electrophysiological response during stimulation (transient increase of the plateau)¹⁴. All these observations indicate clearly that ATP exerts its action at different levels during synaptic activity.

Voltage clamp study on inward chloride currents of spherical muscle cells in tissue culture

EMBRYONIC chick skeletal muscle fibres grown in tissue culture generate three types of action potential different in their underlying ionic mechanisms and which are known accordingly as Na, Ca and Cl spikes¹. Because of their irregular and cylindrical shape^{2,3} these muscle fibres are not suitable for further analysis of the ionic mechanisms in using voltage clamp techniques. Voltage clamp techniques could however be applied successfully to those cultured muscle cells which, after incubation in a medium containing colchicine, had become spherical

myosacs²⁻⁶. In preliminary studies, the myosac generated Na, Ca and Cl spike components² and also, under voltage clamp, a late inward current (LIC) not necessarily due either to Na or to Ca (ref. 3). I now report a further voltage clamp study of the myosac revealed that the amplitude of the LIC was related to the concentration gradient of Cl ions across the cell membrane, and that the LIC was generated by a slow increase of Cl conductance which was dependent not only on the membrane potential, but also on the time course of the membrane depolarisation. Such Cl conductance provides the basis for the generation of a regenerative Cl spike in tissue-cultured skeletal muscle cells.

Fig. 1 Two myosacs on the 7th day in tissue culture. 10^{-8} M colchicine was added to the tissue culture medium during the 4th and 6th day of muscle development. Phase contrast microscope. Scale: 50 μ m.

Myoblasts (3×10^5 to 4×10^5 cells ml^{-1}) were obtained from pectoral muscles (dissociated mechanically) of 10–12-d old chick embryos and grown on a collagen-coated plastic dish (Falcon) in a modified Eagle's minimum essential medium⁷. Colchicine (10^{-8} M final concentration) was added to the medium during the 4th and 6th day of tissue culture, and the original long multinuclear myotubulus developed into independent myosacs 10–200 μ m in diameter (Fig. 1).

A myosac was penetrated with two glass microelectrodes (8 to 15 M Ω) filled with either 3 M KCl or 3 M K acetate solution. Membrane currents were measured with conventional voltage clamp techniques^{3,8}. To prevent possible inactivation of spike generation at low resting potentials² (-50 to -60 mV), the myosac was kept hyperpolarised to between -70 and -100 mV (holding membrane potential) by injecting steady currents of 2 to 10 nA (holding current). This holding current was also used for an injection of anions contained in the microelectrode into the myosac. The ionic composition in the bathing solution (NaCl 128.4 mM, KCl 5.0 mM, CaCl_2 5.0 mM and Tris-Cl 15.0 mM at pH 7.4) were altered under the voltage clamp condition.

Figure 2a–f illustrates the membrane currents generated by stepwise changes of the intracellular potential from the holding potential (-90 mV) to various levels. In this experiment, the microelectrodes were filled with 3 M K acetate solution. For small ranges of depolarisation or hyperpolarisation, the membrane currents consist of a transient capacitive current which lasts for a few ms (not visible in the figure) and a steady leakage current (Fig. 2e and f). When the membrane depolarisation exceeds a certain level (threshold), a LIC is seen superimposed on the two currents above. The LIC reaches its maximum amplitude of 2–5 nA in 1 to 10 s after depolarisation and decays thereafter to a level of the leakage current (Fig. 2d); the generation of the LIC is apparently time dependent. The same LICs can be generated repeatedly if the interval between the depolarisation is sufficiently long (usually 60–100 s). By increasing the depolarisation (Fig. 2d–a), the LIC becomes smaller in ampli-

Fig. 2 Membrane currents and the I–V relationship examined under voltage clamp. a–f, Membrane currents elicited by instantaneous changes of the intracellular potential from the holding potential (-90 mV; holding current, 3.5 nA) to the levels indicated on each records. LIC is seen maximum amplitude in d. ●, Amplitudes of the peak inward currents or of the least outward currents (marked below records) during the depolarisation. ○, Amplitude of the currents measured at the end of the depolarisation. K acetate-filled microelectrodes were inserted into a myosac on the 5th day in tissue culture. See text for further details.

tude (Fig. 2c) and finally, most of the membrane currents become outward during a large depolarisation (Fig. 2a and b). It should be noted that shortly after the depolarisation, the myosac generated a transient inward current (50 to 200 nA) lasting 1–5 ms; this inward current, which was shown to be carried by Na ions³, is not seen in the figures of this paper because of the slow sweep velocity.

Figure 2g is an I–V relationship of the membrane currents obtained by plotting (1) the peak inward currents or the least outward currents and (2) the currents measured at the end of the depolarisation of Fig. 2a–g against the membrane potentials. The plots for the peak of the LICs form the N-shaped curve in Fig. 2g. This indicates that the LICs are generated as a result of an increase in the membrane conductance which represents the negative resistant part of the I–V curve and that this conductance increase is depended on the membrane potentials.

The LIC in Fig. 2 reaches its maximum amplitude between -50 and -60 mV. The maximum LIC was tested in the following ways. When Cl ions were injected into a myosac by means of a nearly steady current (holding current; see above) through a KCl-filled microelectrode, the amplitude of the LIC increased

Fig. 3 Increase in amplitude of LICs associated with changes of Cl ion concentration. a–b, Intracellular injection of Cl ions by holding membrane current (about 4 nA) through a KCl-filled microelectrode caused a gradual increase in the amplitude of LICs elicited by the membrane depolarisation from -85 mV to -55 mV. a and b were recorded 5 and 11 min after the onset of the Cl injection, respectively. A myosac on the 6th day in tissue culture. c–d, Decrease of the extracellular Cl ion concentration (replaced by acetate ions) from 158.4 mM (c) to 15.0 mM (d) caused the increase in the amplitude of the LICs elicited by the membrane depolarisation from -75 mV to -56 mV. Before recording c, the myosac (on the 7th d in tissue culture) was loaded with Cl ions by 2 to 3 nA holding current for about 15 min, and the LICs became steady in amplitude. The solution change from c to d was performed in 3 min.

in time. This is shown in Fig. 3*a* and *b* by comparing the LIC elicited at about 11 min (*b*) with that at 5 min (*a*) after the onset of the Cl injection. In spite of the increase in amplitude, the time course of the membrane currents remained almost constant during the injection of Cl ions (Fig. 3*a* and *b*). Such an increase in amplitude of the LICs, however, did not occur (or rather decreased slightly) in the control experiments where acetate ions, instead of Cl ions, were injected intracellularly through a K acetate-filled microelectrode (not illustrated). Since acetate ions are considered impermeable through various Cl-permeable membranes⁹⁻¹¹, the increase in the amplitude of the LIC described above could be attributed to an elevation of Cl ion concentration in the intracellular space of the myosac.

The amplitude of the LIC became almost steady after about 10–15 min of the Cl-loading procedure. When Cl ion concentration in the bathing solution was decreased by replacing Cl ions with an equimolar solution of acetate (or propionate) ions, the LICs increased further in amplitude (Fig. 3*c–d*). But an alteration of the cation species in the bathing solution, such as Na (replaced by Tris), K (replaced by Na in the range 2–20 mM) or Ca (replaced by Na in the range 2–20 mM) ions, did not induce a significant increase in the amplitude of the LICs (not illustrated). These observations indicate that the amplitude of the LIC is related to both the intracellular and extracellular concentration of Cl ions, namely the concentration gradient of Cl ions across the myosac membrane.

It should be pointed out that the LICs were elicited under conditions in which the membrane potential was held at a hyperpolarised level below its resting membrane potential and the myosac was loaded with Cl ions. In these conditions, the electromotive force of the LICs, E_{Cl} , would be more positive than the holding membrane potential. An increase in the Cl conductance at the membrane potential depolarised below E_{Cl} would therefore generate an inward current³. It should also be mentioned that the net flux of the Cl ions during a LIC was directed outward.

The slow time course (that is, the peak time and duration) of the present LICs obtained in the voltage clamp experiments is compatible with the slow rise time and long duration of the Cl spikes elicited in the myosac under a current clamp condition. In fact, when a myosac was examined under the voltage clamp and current clamp conditions, the reversal potential of the LIC coincided closely to the peak membrane potential of the Cl spike³. These observations support the idea that the Cl conductance underlying the LIC is responsible for generation of the Cl spikes in cultured skeletal muscle fibres.

Inward Cl currents generated in *Nitella* and *Chara*¹²⁻¹⁴, and in electric organs of fish¹⁵ resemble the present LIC with respect to the time course and the dependency on the membrane potentials. Although the direction of currents is outward, a similar slow increase in Cl conductance has been reported in mature frog skeletal muscles^{16,17} and in sheep heart muscles¹⁸. The physiological role of the increase in the Cl conductance is not known for certain. Cl conductance may have a role in the coupling between the excitation and contraction¹⁹⁻²¹ or in the differentiation and maturation of muscle cells.

I thank the US National Institutes of Health for support, Drs T. G. Smith, K. Toyama and J. Leung for discussion, and Mrs M. F. Neal for help with the tissue culture. J.F. was supported by a Visiting Associateship from the Fogarty International Centre.

Ionic permeability changes occurring at excitatory receptor membranes of chemical synapses

ALTHOUGH the ionic basis for generation of action potentials in nerve and muscle cells is now well understood¹, there is still much uncertainty about the changes in ionic permeability which result in the generation of graded depolarisations at receptor membranes of excitatory chemical synapses². The equilibrium potential for these graded depolarisations (E_R) is usually between -20 and $+10$ mV. This suggests an underlying increase in sodium permeability (P_{Na}) and potassium (P_K) and/or chloride (P_{Cl}) permeability, for in most nerve and muscle cells, the sodium equilibrium potential (E_{Na}) is very positive ($+50$ to $+75$ mV) and the potassium and chloride equilibrium potentials (E_K and E_{Cl}) are very negative (-40 to -100 mV). There is evidence that an increase in P_{Na} does occur during activation of excitatory synaptic membranes³, but there are few such membranes for which there is evidence for an increase in either P_K or P_{Cl} . Here we review and analyse the data obtained from previous investigations on the ionic basis of the graded depolarisations occurring at excitatory synapses. We demonstrate that the application of the Goldman-Hodgkin-Katz equation³⁻⁴ to previous data suggests that an increase in P_K as well as P_{Na} probably occurs at most if not all excitatory synapses.

At the vertebrate endplate, the transmitter substance and acetylcholine cause an increase in sodium and potassium conductance (Δg_{Na} and Δg_K), and

$$\frac{\Delta g_{Na}}{\Delta g_K} = \frac{E_K - E_R}{E_R - E_{Na}} \quad (1)$$

$\Delta g_{Na}/\Delta g_K$ remained constant during changes in external sodium concentration $[Na]_o$ and external potassium concentration $[K]_o$ between 5–150 mM and 0.25–7 mM respectively^{5,6}, with tenfold changes in $[Na]_o$ and $[K]_o$ within these concentration ranges causing shifts of E_R of about 30 and 25 mV respectively^{5,6} (Figs 1 and 2). Similar results were obtained at two other nicotinic cholinergic excitatory synapses, namely synapses generating the fast excitatory postsynaptic potentials in the frog sympathetic ganglion⁷, and the annelid neuromuscular junction⁸ (Figs 1 and 2).

For many other synapses, however, such as several cholinergic synapses in the molluscan central nervous system⁹⁻¹¹, glutamate synapses of insect^{12,13} and crustacean¹⁴ excitatory neuromuscular junctions, and mammalian smooth muscle cholinergic junctions¹⁵, E_R was altered by changes in $[Na]_o$, but not by changes in $[K]_o$ or $[Cl]_o$ (Figs 1 and 2). For example, in voltage clamp studies of the insect neuromuscular junction¹², E_R for the glutamate current and the excitatory postsynaptic current was $+3$ and $+4$ mV respectively in normal saline. In 0% NaCl, E_R for the glutamate current was $+8$ mV. E_R was not, however, altered when $[Cl]_o$ was decreased by 100% or when $[K]_o$ was changed between 0 and 20 mM. Consequently, it has been suggested that the synaptic current at all of

Fig. 1 Equilibrium potential (E_R) of the synaptic potentials and currents at different sites in different external concentrations of sodium, $[Na]_o$. The line represents a slope of 58 mV per tenfold change in $[Na]_o$. Most of the values of E_R are below both this 58 mV slope predicted by the Nernst equation if just Na was carrying the synaptic current, and also below the 50–57 mV slope predicted by the Goldman-Hodgkin-Katz equation if both Na and K were carrying the synaptic current (see Fig. 3). Abscissa: $[Na]_o$ (log scale). Ordinate: change in E_R . The data have been obtained from the following sources: ●^{6,8}, ○¹¹, △¹⁰, ▽¹⁴, ▽⁷, ○⁸, +⁸, ◆¹², ▲¹¹, ■¹³.

these sites was probably due exclusively to Na activation⁹⁻¹⁵. There are also several other excitatory synaptic membranes at which it has been concluded that only Na carries the current during activation (for review see refs 2 and 16).

The 'membrane conductance' of an ion depends not only on the membrane permeability for that ion but also on the concentration and distribution of that ion on either side and within the membrane¹. Changes in $[Na]_o$ and $[K]_o$ would therefore be expected to affect the membrane conductance but not the membrane permeability of these ions. We have used the Goldman-Hodgkin-Katz equation to predict changes in E_R when $[Na]_o$, $[K]_o$ and $[Cl]_o$ are altered at the crustacean neuromuscular junction, the molluscan central nervous system and the squid giant synapse, using the data of previous investigators^{10,14,17}. These sites were chosen as they illustrate

in E_R predicted for a constant permeability increase to Na and K are very different from those predicted for a constant conductance increase to Na and K, but they do agree closely with the observed results at many excitatory synapses. We therefore propose that an increase in conductance to both Na and K does occur at excitatory synapses at which E_R lies between E_{Na} and E_K and at which altering $[K]_o$ between 0 and about 200% normal does not cause an observable shift in E_R . At the vertebrate endplate, E_R for the endplate potential at low temperatures (2 °C), and E_R for the action of suberythrolone, a cholinomimetic agonist, are not changed when $[K]_o$ is lowered from 2.5 to 0.5 mM (ref. 18). It was therefore suggested that $\Delta P_{Na}/\Delta P_K$ does stay constant for these conditions when $[K]_o$ is lowered¹⁸.

Although there is much evidence that Na activation occurs

Fig. 2 Equilibrium potential (E_R) of the synaptic potentials and currents at different sites in different external concentrations of potassium, $[K]_o$. Abscissae, $[K]_o$ (log scale). Ordinates, change in E_R . References for symbols as in Fig. 1.

the predictions of the Goldman equation for a large range of permeability ratios and ionic concentrations. The analysis was carried out assuming that a permeability increase occurred to either Na and K (ΔP_{Na} and ΔP_K) or Na and Cl (ΔP_{Na} and ΔP_{Cl}). The values of $\Delta P_{Na}/\Delta P_K$ were calculated in normal saline from the equation:

$$E_R = \frac{RT}{F} \ln \frac{[K]_o + \Delta P_{Na}/\Delta P_K [Na]_o}{[K]_i + \Delta P_{Na}/\Delta P_K [Na]_i} \quad (2)$$

To calculate $\Delta P_{Na}/\Delta P_{Cl}$, the terms for K were replaced by those for Cl. $\Delta P_{Na}/\Delta P_K$ and $\Delta P_{Na}/\Delta P_{Cl}$ were then assumed to stay constant when $[Na]_o$, $[K]_o$ and $[Cl]_o$ were altered. It can be seen from Fig. 3 that the equation predicts that varying $[Na]_o$ and $[Cl]_o$ causes large changes in E_R , whereas varying $[K]_o$ causes little change in E_R . In fact, the theoretical curve for log $[K]_o$ against E_R has a maximum slope of only about 2 mV for $[K]_o$ between 0 and 200% normal. These changes

at the majority of chemical excitatory synapses, the changes in E_R caused by lowering $[Na]_o$ are often much less than those predicted by the Goldman-Hodgkin-Katz equation if Na and K activation occurred (Fig. 1). A possible explanation is that calcium, which usually has a very positive equilibrium potential, is carrying some of the inward current. There is evidence that the synaptic membrane at the vertebrate endplate¹⁹ and at the insect¹² and crustacean^{14,20} neuromuscular junction is slightly permeable to calcium. Alternatively, lowering $[Na]_o$ may cause a reduction in ΔP_K (ref. 20 and R.A. and P.N.R.U., unpublished).

In conclusion we believe that the graded depolarisations recorded at excitatory synapses which involve an increase in conductance normally involves an increase in both P_{Na} and P_K . In addition, an increase in P_{Ca} may occur especially in low $[Na]_o$. The sites that have been examined in sufficient detail can be divided into two categories. In the first category, which seems to include the nicotinic ACh synapses at the frog

Fig. 3 Equilibrium potential (E_R) of the synaptic currents in different external concentrations of Na, K and Cl, as predicted by the Goldman-Hodgkin-Katz equation. The concentrations of ions and E_R in normal saline were taken from the data of previous investigations. (1) Crustacean neuromuscular junction¹⁴. (2) Molluscan central nervous system¹⁰. (3) Squid giant synapse¹⁷. (4) Crustacean neuromuscular junction (10 mM Na). The curves for Na_1 lie between Na_2 and Na_3 ; K_3 lies very close to the abscissae, and Cl_2 and Cl_3 are very close to Cl_1 . It can be seen that altering $[Na]_o$ and $[Cl]_o$ causes large changes in E_R , whereas altering $[K]_o$ causes little change in E_R , especially between 0 and 200% normal $[K]_o$, the range of concentration used by most investigators. In very low Na (10 mM), altering $[K]_o$ does cause much larger changes in E_R . The slope of the line relating $\log [Na]_o$ to E_R between 50% and 100% $[Na]_o$ is very similar for both the squid giant synapse and the molluscan CNS (57 mV and 52 mV respectively) in spite of $\Delta P_{Na}/\Delta P_K$ being 17.0 at the former and 0.3 at the latter.

and annelid neuromuscular junction and the frog sympathetic ganglion, the increase in conductance ratio to Na and K stays constant when the external ionic environment is modified. In the second category, which includes the acetylcholine synapses in the molluscan central nervous system, insect and crustacean glutamate synapses, and also probably the muscarinic acetylcholine synapses on mammalian smooth muscle, the increase in the ratio of Na conductance to K conductance changes when the external ionic environment is lowered, although the increase of the ratio of Na permeability to K permeability probably stays constant, especially during changes in $[K]_o$.

We would like to thank Dr P. C. Caldwell and Dr B. L. Ginsborg for reading a draft version of this manuscript. This work was supported by a grant from the SRC to P.N.R.U. *Note added in proof:* Ritchie and Fambrough²¹ have found that the acetylcholine reversal potential of cultured rat myotubes can be described by the Goldman equation in media of different $[K]_o$.

Chemical modification of crab nerves can make them insensitive to the local anaesthetics tetrodotoxin and saxitoxin

CONDUCTION of the nervous impulse depends on voltage-sensitive change in the permeability of the nerve cell membrane to sodium ions. The sodium channels that appear during the action potential can be blocked very specifically by various neurotoxins, including tetrodotoxin (TTX) from the puffer fish and saxitoxin (STX) from certain marine algae¹. Shrager and Profera² presented evidence that the binding of TTX to crab nerves is reduced after treatment with a water-soluble carbodiimide and glycine methyl ester as the associated nucleophile. In these chemically modified nerves it follows that the sodium channels should have been rendered insensitive to TTX. Shrager and Profera were unable to test this prediction because in their experiments the nerves became inexcitable after chemical treatment.

We have carried out a similar modification and found conditions in which nerves continue to conduct impulses. Axons treated in such a way have a greatly reduced sensitivity to both TTX and STX, suggesting that either the sodium channel or its immediate environment has been modified such that the binding of both TTX and STX is markedly impaired without appreciably affecting the access of ions to the voltage-sensitive sodium channel.

In all our experiments, a water-soluble carbodiimide was used with various associated nucleophiles. Nucleophiles with pK_s in the neutral range and below were most satisfactory and these included diglycine, triglycine, glycine methyl ester, glycine ethyl ester, imidazole, semicarbazide, orthophosphate and *p*-amino benzene sulphonate.

Nerves were obtained from the walking legs of the spider crab (*Maia squinado*) and exposed to reagents in artificial seawater containing NaCl, 460 mM; MgCl₂, 55 mM; CaCl₂, 11 mM; KCl, 10 mM; NaHCO₃, 2.5 mM; together with 100 mM nucleophile and 100 mM carbodiimide at pH 5.5. After varying lengths of time the nerves were removed, washed well in normal artificial seawater (pH 7.8), and their sensitivity to TTX examined. In many instances treated nerves continued to conduct action potentials in the presence of 0.1 mM TTX, whereas untreated control nerves were blocked by TTX concentrations as low as 50-100 nM. To quantify this observation we used the conduction velocity technique of Colquhoun and Ritchie³. Nerves were mounted on a spaced set of platinum electrodes, and after the reaction, the conduction velocity was measured as a function of the external sodium concentration. In this way it is possible to equate inhibition produced by TTX to an equivalent reduction in external sodium and to obtain a rough estimate of the number of sodium channels that have been blocked, assuming $n=1$ in equation (3) of Colquhoun and Ritchie (Fig. 1).

Two features should be noted. The dose-response curve seems to be made up of two components: one with a normal high affinity for TTX, which presumably reflects unreacted sodium channels, and one with an affinity three

Fig. 1 Dose-response curves for blockage by TTX of sodium channels in crab nerve. Ordinate, reduction in number of functional sodium channels plotted as percentage inhibition; abscissa, concentration of TTX (nM) plotted on a log scale. ●, Control nerve immersed in artificial seawater (ASW); ○, nerve pretreated for 30 min in ASW containing 100 mM glycine methyl ester and 100 mM carbodiimide, pH 5.5 at 21 °C, compound action potentials corresponding to points *a*, *b*, *c*, *d* are shown on the right; □, nerve exposed to previous solution but in presence throughout of TTX (500 nM). After reaction, nerves were washed well in ASW before determining sensitivity to TTX. All nerves were obtained from the same animal.

to four orders of magnitude lower. These modified sites are partly inhibited in the presence of a saturated solution of TTX, but it is possible that at these concentrations TTX or an impurity is acting in a nonspecific manner. Exposure to carbodiimide and a suitable nucleophile while in the presence of a lethal concentration of TTX followed by repeated washing in TTX-free medium restored a conducted action potential that exhibits a sensitivity to TTX comparable with that seen in untreated controls. This observation shows that the presence of TTX protects against formation of the insensitive (or less sensitive) TTX-binding site.

To increase the proportion of sodium channels protected, we carried out the reaction in various conditions. As expected from the known chemistry of the carbodiimide reaction⁴ (Fig. 2), the rate of reaction increases as pH is reduced; but at low pH the nerve suffers irreversible damage even in the absence of reagents. We normally worked at pH 5.3–5.8. In these conditions the reaction rate increased linearly with increasing concentrations of either carbodiimide or glycine methyl ester. Some damage, evidenced by a reduction in conduction velocity, was seen in all preparations after exposure to the carbodiimide either alone or with a nucleophile. Glycine methyl ester alone had no effect on the preparation. Prolonged exposure to carbodiimide eventually blocked conduction, and the onset of this conduction block provided an upper limit to the exposure time. In optimum conditions (100 mM glycine methyl ester, 100 mM carbodiimide pH 5.5 for 30 min) we obtained modification of about 40% of the functional TTX-binding sites. The same treatment rendered a comparable percentage of sodium channels insensitive to another local anaesthetic, STX.

What group in the membrane is involved in generating the observed sensitivity to TTX? In aqueous solution the main groups known to react in the conditions of our experiments are thiols, phenols, amines, phosphates and carboxylates. In general, three reaction schemes are possible (Fig. 2.).

(1) The reactions with thiols, phenols and amines yield stable products without any added nucleophile³. It follows that reaction with carbodiimide alone should lead to a reduction in sensitivity to TTX, but this is never seen. Nerves exposed to carbodiimide alone slowly become in-

excitable, which may result from these reactions, or, conceivably, from reaction with a surface phosphate group either by effecting cyclisation of a phosphate with an adjacent *cis* hydroxyl or formation of a N-phosphorylurea^{4,6}. (2) The carbodiimide reaction with carboxyl groups yields an unstable intermediate which will react with a nucleophile. When the nucleophile is a primary amino compound the reaction should give a stable amide bond. Condensates with secondary amino compounds will be less stable. If, however, the nucleophile is orthophosphate, the product should be an acylphosphate which would be expected to hydrolyse at pH 5.5 with a halftime of less than one hour⁷. (3) With membrane phosphate groups, condensation with primary and secondary amines will form phosphoramidates; condensation with carboxyl will form acylphosphate; and condensation with orthophosphate will form pyro- or polyphosphates. Although the phosphoramidates are stable at pH 7 (refs 8–11), both acyl- and pyrophosphate are relatively easily hydrolysed^{7,12,13}.

There are problems in distinguishing experimentally between membrane-bound phosphate and carboxylate. A short-lived reduction in sensitivity to TTX (30 min) was seen after condensation with orthophosphate, which is consistent with both possibilities. In theory these possibilities might be distinguished if protection could be demonstrated after reaction with a carboxylic acid as nucleophile, because anhydrides are generally much less stable in aqueous solution than acylphosphates¹⁴. Condensation with carboxylic acids normally block conduction rapidly; but some protection against TTX was obtained with malonic acid, suggesting that a phosphate group may be involved. In addition, although not yet allowing further discrimination, we find that reaction with Meerwein's reagent (triethyloxonium tetrafluoroborate) also renders nerves insensitive to TTX.

The observation that TTX is able to protect against the chemical modification produced by carbodiimide and a suitable nucleophile raises the possibility that this might provide a convenient means of attaching a covalent label to the sodium channel. Thus, if a nerve is exposed to

Fig. 2 Possible reaction schemes involving membrane components, carbodiimide and nucleophiles. R, Unknown component of the membrane; R', ethyl; R'', dimethylaminopropyl; B, various nucleophiles.

Fig. 3 Binding of ³H-glycine methyl ester to crab nerve. Nerves were exposed to ASW containing 100 mM carbodiimide and 100 mM glycine methyl ester at pH 5.5. After incubation, nerves were washed well in ice-cold ASW containing non-radioactive glycine methyl ester, homogenised in distilled water to release any free intracellular label and centrifuged. The pellet was washed twice with distilled water containing 10 mM ester, dissolved in Nuclear Chicago Solvent and counted. Temperature 21 °C. Uptake shown by dotted line was obtained after exposure of the nerve for 90 min to non-radioactive reaction mixture.

carbodiimide and glycine methyl ester in the presence of TTX, subsequent removal of the TTX and re-exposure to carbodiimide and labelled glycine methyl ester might result in specific labelling of the sites previously protected by the TTX. We tested this possibility by making the methyl ester of ³H-glycine using Fischer's method¹⁵, and measuring the uptake of label after reaction with crab nerve in optimal conditions. Figure 3 shows that uptake continued for many hours and that considerable radioactivity became associated with the nerve. If the uptake is expressed in terms of the available nerve membrane area¹⁵, after 60 min the uptake is equivalent to 10¹⁴ labelled molecules per cm² or 10⁶ per μm² or 1 molecule per 100 Å². The number of sodium channels has been estimated to be about 100 per μm² (refs 1, 17, and 18) and it is perhaps not surprising that we were unable to detect any significant differences in the uptake of ³H-glycine methyl ester between nerves pre-exposed to cold nucleophile in the presence or absence of TTX.

Labelled nerves provided further information on the nature of the covalent bonding. The majority of the label was stable to acid (1 h, pH 3.0), alkali (1 h, pH 10) and to neuraminidase; but was largely solubilised following exposure to a number of proteolytic enzymes including Pronase (Sigma Protease, Type V), trypsin and chymotrypsin, indicating that the label is mainly attached to proteins and polypeptides. The high density of these groups is somewhat unexpected although there is electrophysiological evidence for a similar number of negatively charged groups at the inner face of the squid axon membrane.

Our results show that a relatively straightforward chemical modification of the axon can lead to a dramatic change in its sensitivity to TTX and STX without affecting its voltage-sensitive permeability to sodium ions. This may help explain the relative insensitivity of some excitable cells to these toxins¹⁹. In its present form the carbodiimide-labelling technique produces too much nonspecific label to be of real use in isolating sodium channels, but it is probable that if the technique outlined here, or some modification of it, were applied to a partially purified preparation of TTX-binding sites it may be possible to attach a covalent label to the sodium channels that would aid purification of

these channels while still retaining their characteristic voltage-sensitive permeability to sodium ions.

Direct evidence of importance of lysosomes in degradation of intracellular proteins

THE mechanisms of breakdown of intracellular proteins are largely unknown. It is widely presumed that lysosomes are important agents of this process¹, chiefly because they contain suitable enzymes². Although autophagic uptake and degradation of cytoplasmic organelles by lysosomes has been described¹, there is only circumstantial evidence for significant lysosomal involvement in turnover of intracellular proteins³⁻⁶. Indeed, it is difficult to explain the heterogeneous turnover rates of proteins⁷ by a process involving bulk uptake of material¹. Furthermore, there is evidence for alternate systems of intracellular protein breakdown^{5,8}. In contrast, it has been shown that macrophage lysosomes are largely responsible for the degradation of endocytosed proteins, and that cathepsin D participates⁹. In the work reported here, breakdown of endogenous proteins of the perfused rat liver has been retarded by a specific inhibitor of cathepsin D, directed to the lysosomes, thus demonstrating their importance in the process.

The pentapeptide pepstatin¹⁰ is an inhibitor of carboxyl proteinases (termed acid proteinases by Hartley¹¹, because they generally have acid pH optima) such as cathepsin D¹². Cathepsin D, a lysosomal² enzyme with optimum activity near pH 5, adapted to the probably acidic lysosomal milieu, is the only known carboxyl proteinase in rat liver. Data on neutral proteinases^{1,3}, which might be capable of proteolysis in the cytoplasm, continue to appear. But with the exception of the specific kidney endopeptidase renin (which is now known to be a carboxyl proteinase¹³), none of these enzymes is inhibited by pepstatin. Thus pepstatin has no effect on autoprolysis of rat liver cytosol proteins at neutral pH⁶. The time course (up to 4 h) of digestion of a cytosol protein mixture⁶ at neutral pH (where cathepsin D is inactive) by sonicated rat liver homogenate (5 mg protein per ml) in the presence of 1% Triton X-100 has now also been found to be unchanged by pepstatin (0.1-10 μg ml⁻¹). Pepstatin is therefore suitable for the specific inhibition of rat liver cathepsin D.

Table 1 Rate of output of TCA-soluble radioactivity

Addition made at 105 min	Rate of output	
	% Initial rate	Average of group (% initial rate \pm s.d. (n))
(a) None	97	100 \pm 4 (3)
	105	
	99	
(b) 2 ml 5 mM potassium phosphate buffer, pH 7.0, containing pepstatin (50 μ g ml ⁻¹)	107	101 \pm 6 (3)
	95	
	101	
(c) 2 ml control liposomes	81	93 \pm 13 (3)
	108	
	90	
(d) 2 ml liposomes containing pepstatin (50 μ g ml ⁻¹)	32	47 \pm 17 (3)
	66	
	44	

Perfusions and additions were as described for Fig. 1. Rats were 250–300 g body weight. Initial rates of output were between 2.6 and 4.7 d.p.m. per ml medium per min, and corresponded to the release of 2–3% of initial liver protein radioactivity per hour. Correlation coefficients for the lines for perfusions in the absence of liposomes or in the presence of control liposomes were between 0.94 and 0.99. Those for periods after treatment with liposomes containing pepstatin were lower (0.87–0.94), probably because inhibition was not immediate. Leakage of malate dehydrogenase during the perfusion was always less than 3%, confirming the integrity of the livers. Livers receiving entrapped or free pepstatin were further perfused with a single pass of 0.9% NaCl (100 ml) at 130 min, and then homogenised in 5 volumes of 0.25 M sucrose 50 mM potassium phosphate buffer, pH 7.5. Inhibition of cathepsin D in the homogenates was estimated by assaying aliquots before and after dialysis against 50 volumes of phosphate buffer, pH 7.5, with one change. At pH above 6.4, there is little binding of pepstatin to cathepsin D (C. G. Knight, personal communication) and thus dialysis allows recovery of activity. The enzyme in homogenates of livers receiving liposomal pepstatin was approximately 80% inhibited, and that from livers receiving free pepstatin was approximately 30% inhibited. These values probably overestimate the degree of inhibition achieved in the perfusion since homogenisation will bring all uncomplexed inhibitor into contact with enzyme (as indicated by the inhibition of homogenate enzyme observed after treatment with free pepstatin, in the absence of inhibition of protein degradation). The percentage rates produced by treatments (a)–(c) do not differ significantly from 100%, whereas those following (d) are significantly different from those following (c) ($P < 0.05$).

Furthermore, pepstatin seems not to permeate macrophage plasma membranes (personal communication from A. J. Barrett and C. G. Knight) or other cellular membranes (with the possible exception of those of erythrocytes infected with malarial parasites¹⁴). Therefore it probably does not permeate lysosomal membranes, as might be expected for a pentapeptide¹. Because of this impermeability it was possible to direct the pepstatin specifically to lysosomes by entrapping it in multilamellar liposomes¹⁵ which are known to enter liver lysosomes rapidly after intravenous injection¹⁶. After endocytosis by Kupffer and parenchymal cells¹⁶, secondary heterolysosomes containing liposomes are formed, and by subsequent fusions, the liposomes also reach autophagic secondary lysosomes¹⁶. This method of administration further reduces the possibility of inhibition of unknown carboxyl proteinases outside the lysosome, by limiting access of the inhibitor to the cytoplasm.

It has been shown⁴ that livers of rats prelabelled with ¹⁴C-valine (given 2–4 h previously) lose labelled valine to the medium on subsequent perfusion. During perfusion in the presence of 15 mM cold valine (to prevent reincorporation) the linear rate of output of radioactivity is proportional to the rate of proteolysis in the period from 60 to 180 min after commencement. Radioactive secretory proteins have left the liver, and been taken up again to a negligible extent⁴ (my unpublished work). The method therefore measures the rate of degradation of intracellular proteins. I have determined this rate during

a 45-min period, and at 105 min from the start of perfusion, added liposomes containing pepstatin, or control liposomes, or free pepstatin, to the medium, and measured the subsequent rate. Figure 1 shows the results of a pair of such perfusions, and Table 1 summarises the results.

In perfusions to which control liposomes or free pepstatin were added at 105 min, there was no significant difference between the rates before and after the addition (Table 1). In contrast, there was a highly significant inhibition by liposomes containing pepstatin (Fig. 1, Table 1). The lack of inhibition by free pepstatin (Table 1b) supports the suggestion that pepstatin does not permeate liver cell membranes.

Fig. 1 Livers from rats prelabelled (2.5–3.5 h) with L-1-¹⁴C-valine (25 μ Ci) were perfused by a minor modification (addition of amino acids to a quarter of their concentration in DMEM, Flow Laboratories, Irvine, Scotland, and glucose, 14 mM, to the medium) of an established technique¹⁷. Medium radioactivity soluble in 5% trichloroacetic acid–10 mM valine (cold) was determined in samples (0.5 ml) taken every 5 min. The arrow indicates the addition of cationic liposomes (20 μ mol phosphatidyl choline, 20 μ mol cholesterol and 10 μ mol stearylamine, in 2 ml 5 mM potassium phosphate buffer, pH 7.0) which probably maintain a fairly constant intrahepatic concentration after a short time¹⁸, and which may reach parenchymal¹⁶ in addition to Kupffer cells. To prepare liposomes¹⁸, lipids (in chloroform-methanol, 2:1) were dried on to the surface of a glass homogeniser in a nitrogen stream, and desiccated under vacuum. After homogenisation (ten passes of a tight pestle) in buffer with pepstatin, 50 μ g ml⁻¹ (●; see also Table 1d) or in buffer alone (○; Table 1c), they were sonicated for 10 s, and used without further treatment. Entrapment of 20–30% of the pepstatin was demonstrated by gel filtration on Sepharose 4B in 0.9% NaCl, which separates free pepstatin from liposomes. Pepstatin was estimated¹⁹ by measuring the activity of various known amounts of human cathepsin D in the presence of column fractions treated with 0.1% Triton X-100 to lyse liposomes. Latency of liposomal pepstatin was confirmed by refiltering entrapped pepstatin after lysis. Because a similar degree of capture of the anionic pepstatin was also observed with anionic liposomes (10 μ mol phosphatidic acid in place of stearylamine) its association with liposomes was probably not merely electrostatic. Line fitting was done by the method of least squares.

These results constitute the first direct evidence that degradation of intracellular proteins in liver is to a large extent performed by lysosomes. They also re-emphasise the role of cathepsin D in digestion of complex substrates, complementing work on cathepsin B₁ and other proteinases⁵. Although perfusion itself increases intracellular proteolysis⁴, the inhibition by pepstatin is great enough to indicate inhibition of both basal and stimulated proteolysis.

It seems probable that entry of proteins into lysosomes is normally the rate limiting step in lysosomal protein breakdown^{1,6}, particularly in view of the lack of evidence for escape of proteins from lysosomes. In the presence of inhibitors of lysosomal

proteinases, intralysosomal proteolysis is retarded, either leading to an intralysosomal accumulation of protein or perhaps to a feedback inhibition of uptake. Either of these events may occur also when lysosomal proteinases are genetically defective; that this has not been detected in man¹⁹ implies they are lethal in early embryonic life. The mechanisms of uptake, and their control and specificity, now deserve considerable further attention⁶.

I thank the MRC for support, and Dr Bastien Gomperts for advice.

Synthetic substrate for cyclic AMP-dependent protein kinase

Most hormones and neurotransmitters are thought to stimulate the synthesis of adenosine 3',5'-cyclic monophosphate (cyclic AMP) which in turn activates protein kinases¹. On activation, the protein kinases transfer the terminal phosphate group of ATP to serine or threonine residues in enzymic or membrane proteins involved in metabolic regulation, thereby either activating or inactivating them. Only a few key proteins are phosphorylated^{1,2} which raises the question of the molecular basis for the recognition of a particular serine by the cyclic AMP-dependent protein kinases. Cohen *et al.*² considered this problem with respect to the phosphorylation of phosphorylase kinase and glycogen synthetase and concluded that the cyclic AMP-dependent protein kinase recognises some specific three-dimensional configuration formed by a particular amino acid sequence at the site of phosphorylation. The features of this structure, however, remain to be defined. It has been shown³ that small peptides from myelin basic protein could act as substrates, thus reducing the number of parameters for consideration.

A major site of phosphorylation by cyclic AMP-dependent protein kinase in intact myelin⁴, isolated myelin basic protein⁵, and in peptic peptides⁶ was serine 110 in the sequence Gly–Arg–Gly–Leu–Ser–Leu. Here we examine the phosphorylation of a synthetic peptide equivalent to amino acid residues 106–113 in the basic protein of human myelin⁷. The peptide is thus the first synthetic substrate for the cyclic AMP-dependent protein kinases which seem to be so important in regulatory processes.

The peptide Gly–Arg–Gly–Leu–Ser–Leu–Ser–Arg was synthesised by the solid phase technique⁸, as modified for auto-

matic synthesis (M. D. Geier, F. S. Geier, and J.D.Y., unpublished). The double coupling programme included chloroform as solvent, dicyclohexylcarbodiimide as coupling agent, 25% trifluoroacetic acid to remove *t*-butyloxycarbonyl protecting groups and anhydrous HF at 0 °C for 30 min to cleave the peptide from the resin and to remove the O-benzyl and nitro groups from serine and arginine respectively. Initial purification was on Sephadex G-15 and the yield was 20%. The peptide was stained with ninhydrin and had a mobility of +0.59 relative to aspartic acid⁹ on high-voltage electrophoresis using Whatman 3MM paper in pyridine–acetate buffer, pH 6.5. Two minor contaminants with relative mobilities of +0.34 and +0.65 were removed by this technique. (These contaminants, which also acted as substrates for the protein kinase, presumably arose from the incomplete removal of the nitro-protecting group on the C-terminal arginine¹⁰.) The purified peptide on analysis contained equimolar ratios of its four constituent amino acids.

Protein kinases were prepared from bovine cardiac muscle and brain^{3,11} and further purified by gel filtration on Sepharose 4B in 5 mM potassium phosphate buffer, pH 7.0, containing 2 mM EDTA. The kinases were assayed with histone and with myelin basic protein as substrates and cyclic AMP produced a stimulation between four- and sevenfold.

In the experiments with synthetic peptide, the electrophoretic assay for protein kinase activity was used³. The actual incubation conditions are described in Fig. 1 and below. The peptide (250 nmol) was incubated with γ -³²P-ATP (1 μ mol, 8.7×10^6 c.p.m.), cardiac protein kinase (8.5 μ g), 4 nmol cyclic AMP, 1.4 μ mol magnesium acetate, 120 nmol EGTA, in 30 mM sodium acetate buffer, pH 6.5, in a total volume of 350 μ l at 30 °C for 2 h. The mixture was fractionated by preparative paper electrophoresis as described above and the paper sheet

Fig. 1 Production of phosphorylated peptide Gly–Arg–Gly–Leu–Ser(P)–Leu–Ser–Arg; ordinate refers to the total nmol of phosphopeptide produced at 30 °C in each incubation tube in 5 min or, in *d*, for the time indicated. In *a*, *b* and *c* 10 μ l of each of the solutions (i), (ii) and (iii) were incubated in separate tubes with 10 μ l of cardiac protein kinase (85 μ g ml⁻¹). Incorporation of ³²P into the peptide was assayed on 25 μ l samples by the electrophoretic method³. *a*, Effect of ATP: (i) peptide in water (10 nmol per 10 μ l); (ii) 14 mM magnesium acetate, 1.2 mM EGTA and 40 μ M cyclic AMP, adjusted to pH 6.5, and (iii) γ -³²P-ATP (3.0×10^6 c.p.m. per 10 μ l) mixed with ATP to give the final concentration indicated in 100 mM sodium acetate buffer, pH 6.5. *b*, Effect of cyclic AMP: (i) peptide in water (3.1 nmol per 10 μ l); (ii) as in *a* but incorporating cyclic AMP to give the final concentration indicated; and (iii) 277 μ M γ -³²P-ATP (2.5×10^6 c.p.m. per 10 μ l) in buffer as in *a*. *c*, Effect of peptide: (i) peptide in water to give the final concentration indicated; (ii) as in *a*; and (iii) 2 mM γ -³²P-ATP (3.0×10^6 c.p.m. per 10 μ l) in buffer as in *a*. *d*, Effect of time and cyclic AMP. Two tubes were prepared with the following solutions (i) 5 μ l peptide in water (50 nmol per 10 μ l), (ii) 50 μ l as in *a* or in the second tube as in *a* but without cyclic AMP present; (iii) 50 μ l 2 mM γ -³²P-ATP (1.4×10^6 c.p.m. 50 μ l) in buffer as in *a*, and (iv) 50 μ l cardiac protein kinase. At times indicated 20 μ l were removed for assay.

Table 1 Sites of phosphorylation by cyclic AMP-dependant protein kinases

Substrate		Sequence	Sources of kinase	Ref.
Non-globular substrates				
Histone F1		Arg-Arg-Lys-Ala-Ser-Gly-Pro *	Liver	22, 23†
Histone F2b		Ser-Arg-Lys-Glu-Ser-Tyr-Ser *	Lymphocytes	24
Myelin basic protein	Site 1	Gly-Arg-Gly-Leu-Ser-Leu-Ser *	Muscle	
	Site 2	Gln-Arg-His-Gly-Ser-Lys-Tyr *	and	
	Site 3	Arg-His-Arg-Asp-Thr-Gly-Ile *	Brain	4, 5, 6
RCMM Lysozyme†	Site 1	Tyr-Arg-Gly-Tyr-Ser-Leu-Gly *		
	Site 2	Arg-Asn-Thr-Asp-Gly-Ser-Thr-Asp *	Muscle	21
Protamine	Site 1	Arg-Arg-Arg-Ser-Ser-Ser-Arg * * *		
	Site 2	Ala-Arg-Arg-Val-Ser-Arg-Arg *	Testis	25, 26
Globular substrates				
Phosphorylase kinase	α subunit	Arg-Leu-Ser-Ile-Ser Lys		
	β subunit	or-Gln-Ser-Gly-Ser- or-Tyr Arg Ile	Muscle	2
Troponin I	Site 1	Val-Arg-Met-Ser-Ala-Asp *		
	Site 2	Ser-Val-Met *	Muscle	18, 19
Pyruvate kinase (Liver)		Leu-Arg-Arg-Ala-Ser-Leu *	Liver	17
Glycogen synthetase		Lys or-Gln-Ile-Ser-Val Arg	Muscle	27

*Amino acid residue phosphorylated.

subjected to autoradiography. A zone of radioactivity with a relative mobility of +0.19 was detected. A sample of this zone stained the typical yellow colour given by glycyl peptides. The zone was eluted with 0.01 M NH_4OH and from the incorporated radioactivity and amino acid analysis 1 mol of phosphate per mol of peptide was calculated; the total yield of phosphopeptide was 71 nmol. Successive Edman degradations of the phosphopeptide and electrophoresis of the products at pH 6.5 showed that the phosphate was present as shown in the sequence Gly-Arg-Gly-Leu-Ser(P)-Leu-Ser-Arg. This result was supported by studies with aminopeptidase and thermolysin. An identical labelling pattern was obtained with bovine brain protein kinase.

In these experiments Offord's formula⁹ was used to follow the change in electrophoretic mobility on the addition or removal of charged groups. We found that the average value for the change in charge on the addition of a phosphate group to a peptide was -1.35 at pH 6.5 in pyridine acetate buffer. When the phosphoserine was N-terminal, however, the phosphate group carried a more negative charge (approximately -1.6).

In kinetic experiments the cardiac kinase was used. Human myelin basic protein was used at the same molar concentration as the peptide to enable a comparison to be made. The effect of increasing ATP concentration on the production of phosphopeptide is shown in Fig. 1*a*. Michaelis-Menten kinetics were exhibited and from a double reciprocal plot a K_m value of 2.8×10^{-5} M was determined for ATP, similar to values reported for various protein kinases with proteins as substrates^{12,13}. The K_m found with myelin basic protein was 6.8×10^{-6} M. At high concentrations of ATP, in excess of Mg^{2+} , there was a marked inhibition of the production of

phosphopeptide. A similar effect observed with phosphorylase kinase^{14,15} was attributed to the complexing of Mg^{2+} by ATP.

Half-maximal stimulation by cyclic AMP was produced at 10^{-7} M for both the synthetic peptide (Fig. 1b) and myelin basic protein as substrate. Values ranging from 0.4×10^{-7} to 3×10^{-7} M have been reported for a bovine cardiac protein kinase with histone (calf thymus type IIA) as substrate^{12,13}.

The effect of increasing concentration of synthetic peptide is shown in Fig. 1c. Again Michaelis-Menten kinetics were exhibited and from the linear double reciprocal plot a K_m of 2.4×10^{-4} M for the synthetic peptide with the cardiac enzyme was found. This value is similar to that reported for a peptic peptide substrate³. With myelin basic protein as substrate the K_m was lower (5.3×10^{-5} M). Miyamoto and Kakiuchi¹⁶ found a K_m of 2×10^{-5} M for the protein with a brain kinase. The V_{max} for the synthetic peptide was 1.47 nmol ³²P incorporated per 5 min and for the protein 0.36 nmol ³²P incorporated per 5 min. It should be emphasised that in the protein both threonine and serine sites are subject to phosphorylation⁵ (Table 1), whereas with the synthetic peptide only a single site was phosphorylated, thus the comparison of K_m and V_{max} is of limited value.

The effect of increasing time of incubation on the production of phosphopeptide in the absence and presence of cyclic AMP is shown in Fig. 1*d*. In 1 h very little phosphorylation of the peptide was observed in the absence of cyclic AMP. Thus it seems that the peptide is not able to dissociate the catalytic and regulatory subunits. A similar result was obtained with intact myelin basic protein whereas other studies¹⁶ have reported activation of protein kinase by both this protein and histone. But another sample of the same cardiac kinase as used above that had been frozen and thawed repeatedly showed less cyclic

AMP dependence and much greater activation with time when incubated without cyclic AMP (compare ref. 12).

The synthetic peptide was digested with proteolytic enzymes⁷ or subjected to Edman degradation⁷ and the products examined for substrate activity. Removal of the C-terminal arginine with carboxypeptidase B yielded a peptide, with relative mobility +0.38, which was readily converted to a phosphopeptide with relative mobility -0.06. From the N-terminal end glycine could be removed by Edman degradation without apparent effect on substrate activity, whereas the arginine was essential for activity. This requirement for arginine was confirmed by tryptic digestion, which also destroyed the capacity of the peptide to be phosphorylated. It could be argued that the loss of activity was simply due to the resultant shortening of the peptide but the need for arginine, rather than a neutral amino acid, is supported by the following observations. Although there are numerous serine and threonine residues within quite large tryptic peptides from myelin basic protein, only a few peptides in the tryptic digest were phosphorylated. All the peptides which were not phosphorylated had lysine or arginine to the C-terminal side of the serines whereas those that were phosphorylated contained arginine to the N-terminal side in trypsin resistant bonds⁶. One of these was the peptide Gly-N^G-monomethyl Arg-Gly-Leu-Ser-Leu-Ser-Arg. Preliminary evidence indicated that when the arginine was in the N^G,N^G-dimethyl form phosphorylation of the serine was prevented⁵. Moreover an examination of amino acid sequences around the site phosphorylated by cyclic AMP-dependent protein kinases in a number of non-globular and globular proteins (Table 1) shows that arginine is frequently found close to the serine that is phosphorylated.

Table 1 summarises the amino acid sequences in proteins phosphorylated by cyclic AMP-dependent protein kinases from a variety of tissues. Although in several cases the sequence Arg-X-Y-Ser-Z can be identified, there are also some instances where the arginine is only one residue removed from the serine or one further away. Hjelmquist *et al.*¹⁷ suggested a similar pattern and also that the serine should be surrounded by hydrophobic residues. The latter concept is not fully supported by the data in Table 1. It is puzzling that phosphorylase kinase phosphorylates the same type of site in phosphorylase b and in troponin I yet these sites are not those phosphorylated by the cyclic AMP-dependent protein kinases^{18,19}, which act on other serines in these proteins (Table 1).

Using probability factors listed by Chou and Fasman²⁰ for each amino acid at each position, 1-4, in a β bend, the probability of the sequences listed in Table 1 taking up a β -bend conformation was calculated. Although in several, a high probability emerged for the serine being in position 4 in a β bend, such high probability values were also obtained for sequences around serines in the basic protein which are known not to be phosphorylated.

Sites of phosphorylation in myelin basic protein were independent of the source of the kinase; purified kinases from rabbit skeletal muscle and bovine brain and cardiac muscle all produced the same labelling pattern (Table 1). In some substrates more than one site is phosphorylated at variable rates^{2,4,5,21}; however, no feature is apparent in the more readily phosphorylated sequences. This would suggest that once some minimum requirement is met, the rate of phosphorylation is governed by other factors.

Substrates in Table 1 have been categorised as non-globular and globular but no consistent differences are apparent in the sequences around the site of phosphorylation. Bylund and Krebs²¹ have shown that lysozyme, phosphorylase b and bovine serum albumin contain certain serine residues which are quite inactive as substrates in the native form, but which are readily phosphorylated when the proteins are denatured. This implies that in the native structure the sequence around these particular serines is constrained from taking up the conformation necessary for interaction with the active site of the enzyme. The sequence Arg-X-X-Ser is not a rare sequence

in proteins which do not act as substrates in their native form². Whether the failure of the kinase to phosphorylate these serines is due to the lack of accessibility or to the arginine being, too remote spatially from the serine remains to be determined. Whatever the three-dimensional arrangement of the enzyme-substrate complex, however, we predict the need for a basic amino acid in close proximity to the serine to be phosphorylated. Chemical and physical studies with other synthetic peptides could help solve this problem.

We thank Dr A. B. Caldwell for γ -³²P-ATP. Financial support was provided by grants from the National Multiple Sclerosis Society and from the National Health and Medical Research Council of Australia.

Tubulin requires an accessory protein for self assembly into microtubules

BORISY and Taylor have demonstrated a correlation between the presence of the colchicine-binding protein, tubulin, and the microtubular system of eukaryotic cells¹. Tubulin assembles *in vitro* into microtubules when a brain homogenate is warmed to 37 °C and is supplied with a cofactor, GTP (refs 2 and 3). These microtubules dissociate into tubulin subunits when the solution is chilled to 0 °C (refs 3 and 4), or Ca²⁺ is introduced^{2,4}. Tubulin can thus be purified by repeated cycles of assembly and disassembly^{4,5}. We have found, and others report similarly⁶⁻¹⁰, that some very high molecular weight polypeptides copurify with the tubulin in these conditions.

We have examined the role of these polypeptides in the assembly process and found that separation of the high molecular weight fraction from tubulin prevents self assembly of the tubulin; the colchicine-binding property of the tubulin is un-

affected. The high molecular weight fraction restores assembly competence when added back to the tubulin.

A preparation (for details, see Fig. 1) containing tubulin and the high molecular weight proteins was competent to reassemble into microtubules. We found two characteristic forms present in electron micrographs: 50-nm rings and 10-nm flexible fibres.

Tubulin has previously been reported to exist as dimers (molecular weight 110,000, $s_{20,w}6S$) and in an aggregate form of defined structure, a 49-nm ring complex ($s_{20,w}36S$)^{12,13}. Only 36S tubulin, but not 6S can assemble into microtubules^{12,13}. The 36S form is dissociated by high salt concentration (> 0.8 M NaCl) and reforms if the salt is dialysed away.

We have used this property to separate the constituents of the 36S particle. First, the microtubule pellet was dispersed in homogenising buffer containing 1 M NaCl at 0 °C. The treatment dissociated the 50-nm rings but not the 10-nm fibres, which were removed by centrifugation at 220,000g and 0 °C for 2 h. The supernatant, which was competent to assemble microtubules after the salt was removed, contained tubulin and only one of the high molecular weight polypeptides (Fig. 1d). The proteins were resolved by gel filtration, in the presence of 1 M NaCl on Sepharose 4B (Fig. 2a) or Sephadex G200 (similar, but not shown).

To remove NaCl the fractions were dialysed against medium containing 30 mM MES buffer; 0.2 mM $MgCl_2$; 1 mM EGTA;

Fig. 1 Analysis of microtubule proteins by SDS-polyacrylamide gel electrophoresis. *a*, Whole brain supernatant; *b*, pellet after first assembly step; *c*, supernatant after three cycles of assembly-disassembly, without NaCl; *d*, supernatant after two cycles, 1 M NaCl in second disassembly; *e*, pellet from second cycle disassembly, 1 M NaCl; *f*, peak H from Sepharose 4B column; *g*, peak T from Sepharose 4B column; *h*, marker proteins: 34,000 aspartate transcarbamylase C subunit; 68,000 bovine serum albumin; 130,000 β -galactosidase; 200,000 myosin; *i*, flagellar proteins from *Naegleria gruberi*. Gel electrophoresis was carried out using the procedure of Laemmli¹¹, except that running gels contained only 6.7% acrylamide. Tubulin was prepared from rabbit brains following a method adapted from Shelanski⁹. Excised brains (about 9 g each) from adult rabbits were homogenised at 0 °C in a medium (12 ml per brain) containing 40 mM 2-(N-morpholino) ethanesulphonic acid, adjusted to pH 6.6 with NaOH (MES buffer); 0.3 mM $MgCl_2$; 1.5 mM ethyleneglycol-bis-(2-aminoethyl ether)N,N'-tetra-acetic acid (EGTA); 5 mM 2-mercaptoethanol and 1 mM GTP. The homogenate was centrifuged at 48,000g and 0 °C for 60 min. Glycerol was added (1 ml per 3 ml supernatant) and GTP was replenished (1 μ mol per ml supernatant) and the mixture was incubated at 37 °C for 30 min. Microtubules were collected by centrifugation at 100,000g and 25 °C for 60 min. The pellet was resuspended in homogenising buffer (1.5 ml/brain) at 0 °C to disassemble the microtubules, and was dispersed by agitation and expulsion through a syringe. After 30 min at 0 °C, the suspension was centrifuged at 120,000g and 0 °C for 40 min. Glycerol and GTP were added to the supernatant and microtubules were assembled by incubation at 37 °C as above. The second-stage microtubule pellet was resuspended in dissociation buffer (1 ml/brain) containing 40 mM MES buffer; 0.3 mM $MgCl_2$; 1.5 mM EGTA; 1.5 M NaCl; 5 mM 2-mercaptoethanol and 1 mM GTP. After 1 h at 0 °C, glycerol was added to a final concentration of 20% (v/v).

5 mM 2-mercaptoethanol and 4 M glycerol. GTP was added to the retentates to a concentration of 1 mM and the preparations were examined for microtubule assembly by electron microscopy (Fig. 3). Tested individually, peak H (from Fig. 2a), which contained the high molecular weight protein, and peak T, which contained tubulin, failed to form ring complexes at 0 °C and

Fig. 2 Fractionation by gel filtration of microtubule disassembly products. *a*, Microtubules were disassembled at 0 °C, and products were dissociated by 1 M NaCl. Components were resolved by gel filtration in Sepharose 4B equilibrated in buffer containing 30 mM MES, pH 6.6; 1 mM EGTA; 0.2 mM $MgCl_2$; 1 M NaCl; 5 mM 2-mercaptoethanol and 20% (v/v) glycerol. Peak H contains high molecular weight protein and peak T corresponds to 6S tubulin; *b*, rechromatography of peak T after removal of NaCl, by gel filtration in Sepharose 4B, buffer as for *a*, but without NaCl; *c*, rechromatography of mixture of 1 mg H + 5 mg T, preincubated with 1 mM GTP at 0 °C, column conditions as for *b*; *d*, microtubules disassembled at 0 °C, and products fractionated by gel filtration on Sepharose 4B without NaCl dissociation of 36S rings, buffer as for *b* and *c*.

microtubules after incubation at 37 °C. Tubulin alone was passed again through Sepharose 4B, this time in the absence of NaCl, and eluted in the normal position for 6S dimer (Fig. 2b), indicating that 36S ring complexes had not formed. A mixture of tubulin and high molecular weight protein, allowed to reassociate in the cold in the absence of salt, formed the aggregate which eluted from Sepharose 4B in the position corresponding to 36S rings (Fig. 2c and d). Rings were observed in electron micrographs of the 36S peak (Fig. 3).

Mixtures of the two components incubated at 37 °C formed microtubules in large numbers ($> 10^3/0.003 \text{ mm}^2$ grid). In some cases, the 6S tubulin fraction prepared by Sepharose 4B chromatography formed limited numbers of microtubules ($< 30/0.003 \text{ mm}^2$ grid), but the high molecular weight protein was detected as a contaminant in these samples. Sephadex G200 generally gave a superior resolution of the components.

Early attempts to reconstitute an assembly-competent tubulin-accessory protein complex were unsuccessful until we included 2-mercaptoethanol in the buffers.

We estimate the molecular weight of the accessory protein to be about 360,000 from its mobility in SDS-polyacrylamide gel electrophoresis, by extrapolation from myosin (200,000), our largest available marker. The band matches the mobility of dynein isolated in flagellae from *Naegleria gruberi*. It seems likely that our microtubule accessory protein corresponds to the dynein-like proteins identified in brain tissue, which were also found associated with tubulin purified by the assembly-disassembly cycling procedure^{8,9}. These authors failed to find significant ATPase activity, characteristic of flagellar dynein, associated with their brain "dynein".

Fig. 3 Electron micrographs of tubulin preparations: a, mixture containing tubulin (2 mg ml⁻¹) and peak H protein (0.4 mg ml⁻¹) incubated for 30 min at 37 °C with 1 mM GTP ($\times 9,720$); b, same preparation at higher magnification, showing subunit structure of microtubules ($\times 184,200$); c, supernatant after microtubule disassembly in the third cycle of purification (see Fig. 1c for protein composition): fibres lack any subunit structure similar to microtubules ($\times 40,090$); d, microtubule disassembly in 1 M NaCl, rings have disappeared but fibres remain ($\times 20,350$); e, supernatant after 220,000g centrifugation of NaCl-dissociated tubulin, dialysed and incubated at 0 °C with 1 mM GTP (protein composition shown in Fig. 1d) ($\times 214,800$). Preparations were negatively stained with 0.7% uranyl acetate, on carbon-coated Parlodion grids, with 25 $\mu\text{g ml}^{-1}$ bacitracin as spreading agent.

The extreme size of the polypeptide causes difficulties in gel electrophoresis in many conventional systems and the protein penetrates poorly in gels of too high acrylamide concentration ($> 7\%$) or of too high bisacrylamide-acrylamide ratio. Either condition prevents formation of a distinct band in electrophoresis gels and would account for the failure of other workers to detect the accessory protein¹³.

We have evidence that the accessory protein is incorporated into the structure of microtubules rather than acting as an initiating factor or assembly catalyst. *In vitro* assembled microtubules band in sucrose density gradients at 1.289 g cm⁻³ (R.A.B.K. and R.H.H., unpublished) and both tubulin and the high molecular weight protein coincide with the band. Similarly, the accessory protein coelutes with the ring complex from a column of Sepharose 4B (Fig. 2d), although there is considerable difference in molecular size. When limiting amounts of accessory protein are added to pure tubulin, there is limited assembly into microtubules. These data are, however, based on electron microscopy which is only semi-quantitative and it has not been possible to determine an optimum stoichiometry for maximum reassembly of microtubules. The protein comprises about 15% by weight of intact microtubules (data derived from Fig. 2a), which corresponds to one 360,000 molecular weight protein per forty 55,000 molecular weight tubulin subunits, a ratio which suggests that each ring complex¹³ contains one accessory protein.

The results we describe here confirm the report by Weingarten *et al.* that a protein factor is required in addition to tubulin for microtubule assembly¹⁴. Weingarten found the assembly-promoting activity, tau factor, in a heterogeneous fraction containing many proteins which were not further resolved. Our high molecular weight protein has similar properties to the tau factor in that it permits assembly of 6S tubulin into microtubules at 37 °C and converts 6S to 36S tubulin at 0 °C.

Electron microscopy has failed to detect any large globular protein corresponding to the estimated size of the accessory microtubule protein, although tubulin monomers (55,000) can be distinguished in the structure of the microtubule. We speculate therefore that the accessory protein exists as a thin filament interconnecting the subunits, both in the complete microtubule and in the ring complex. Burns and Pollard⁸ have calculated the Stokes radius of their dynein-like protein from brain microtubules and conclude that it is highly asymmetric. One interesting possibility that emerges is the potential for different forms of accessory protein to modulate the properties of the resulting microtubule, thereby enabling identical tubulin subunits to form functionally distinct classes of microtubule. In this context, the amino acid sequence of tubulin has been found to be highly conserved in examples from widely divergent taxa¹⁵.

'Single-stranded' DNA from ϕ X174 and M13 is cleaved by certain restriction endonucleases

DURING a systematic survey of the substrate specificities of a variety of restriction endonucleases, it was discovered that the *Haemophilus aegyptius* restriction endonuclease III (*Hae*III) specifically cleaved 'single-stranded' DNA from ϕ X174 and M13. Since these DNAs are not double-stranded¹ and restriction enzymes recognise duplex DNA with twofold sequence symmetry², this result was unexpected. This finding is significant with regard to the conformation of single-stranded viral DNA as well as the biochemical mechanism and physiological role of restriction enzymes.

Figure 1 shows a polyacrylamide gel electrophoretogram of the fragments produced by *Hae*III on ϕ X174 replicative form (RF), ϕ X174 (+) strand and M13 (+) strand DNA. For the duplex ϕ X174 RF DNA, nine bands are visible; the smallest fragment is not visible and the sixth band is a doublet thus totalling eleven fragments, as reported previously^{3,4}. Digestion of the 'single-stranded' ϕ X174 (+) DNA with *Hae*III produced eleven visible bands and similar digestion of M13 (+) DNA produced nine (Fig. 1). It was shown previously⁵ that M13 RF was cleaved by *Hae*III into ten fragments. The rate of cleavage of the 'single-stranded' DNAs was not as great as for the duplex RF; a 16 h digestion of the (+) strand DNAs was necessary to give a limit digest, whereas a 1 h period sufficed for the duplex RF. The reason for this difference in rates is unknown at present. Similar patterns were obtained when the *Streptococcus faecalis* restriction endonuclease I (gift of R. Wu) replaced *Hae*III. The cleavage site for both enzymes is GGCC.

Regions of duplex helical structure in the (+) strand DNAs (refs 6-8) seem to provide suitable sites for the specific cleavages. Heat-treated λ plac 5 DNA was not degraded, whereas the native double-stranded DNA was degraded to more than 50 specific fragments by *Hae*III in identical conditions. If, however, ϕ X174 (+) DNA was heated (98 °C for 5 min in 5 mM sodium phosphate (pH 7.4)-10 μ M EDTA) followed by quick chilling in ice before treatment with *Hae*III, it was degraded similarly to the untreated DNA. The ϕ X174 DNA seemed to reform appropriate duplex restriction sites readily whereas λ DNA did not. We cannot at present rule out the possibility that a single-stranded non-helical DNA is cut at a slow rate; however, the necessity of a duplex helical structure was shown also by studies with *Hpa*II (B. Baumstark, R. Roberts and U. Rajbhandary, unpublished) and *Eco*RI (ref. 9) on appropriate synthetic substrates. Details of the mechanism of cleavage of 'single-stranded' DNAs are uncertain at present and are currently being investigated.

Fig. 1 Polyacrylamide gel electrophoresis of ϕ X174 RF, ϕ X174(+), and M13 (+) DNAs digested with *Hae*III. Both ϕ X174 DNAs contained *am*3 and *ts*41D mutations (gifts of J. Dodgson and I. Nes); M13 (+) DNA was prepared as described previously¹⁰. The purification of *Hae*III was essentially as described by Roberts *et al.*¹¹ but in addition, the final enzyme stock solution was made 0.5 mg ml⁻¹ in bovine serum albumin. Each DNA sample (2 μ g) was incubated at 37 °C for 18 h in a 50 μ l reaction mixture containing 6 mM Tris-HCl (pH 7.9), 6 mM MgCl₂, 1 mM dithiothreitol and 6 U (ref. 11) of *Hae*III. Digestion was terminated by addition of EDTA to 50 mM. Each sample was made 15% (v/v) in glycerol and 0.03% (w/v) in bromophenol blue, then subjected to electrophoresis in 4% polyacrylamide cylindrical gels in Tris-borate EDTA buffer (90 mM Tris-borate (pH 8.3), 2.5 mM EDTA)¹² for 4 h at 200 V. The polyacrylamide gels (0.6 \times 10 cm) were 3.8% (w/v) in acrylamide, 0.2% (w/v) in N,N'-methylene bisacrylamide (Bis), and were prepared in Tris-borate EDTA buffer-25% glycerol. After electrophoresis the gels were stained for 10 min with 10 μ g ml⁻¹ ethidium bromide and photographed during ultraviolet irradiation. Electrophoresis was from left to right; bromophenol blue migrated to 90% of the length of the gel.

*Hae*III specifically cuts the 'single-stranded' DNA into fragments of the same size as produced by cleavage of the RF. Figure 2 shows a formamide-polyacrylamide gel electrophoretogram of parallel *Hae*III digests of ϕ X174 duplex and 'single-stranded' DNA. The patterns on these denaturing gels are superposable except for the presence of two additional fragments (450 and 150 nucleotides in length; see arrows, Fig. 2) in the (+) strand pattern. It is thus assumed that both the RF and (+) strand are cleaved at the same GGCC sites, with the exception of the two additional fragments; the origin of these two fragments is unknown. The presence of the 450 and 150 nucleotide fragments was also observed as the fifth and eighth bands from the origin, respectively, in the non-denaturing gel (Fig. 1).

The following observations are consistent with the notion that *Hae*III, and not a contaminating enzyme, is specifically cutting the 'single-stranded' DNAs: 1, the similarity of fragment patterns for RF and (+) strand DNA (described here); 2, the

Table 1 Effect of restriction endonucleases on ϕ X174 and M13 DNAs

Enzyme	Recognition sequence	Number of fragments			
		ϕ X174 RF	ϕ X174 (+)	M13 RF	M13 (+)
<i>Haemophilus aegyptius</i> (<i>Hae</i>) III	GGCC	11	11	10	9
<i>H. haemolyticus</i> (<i>Hha</i>) I	GCGC	≥ 14	≥ 14	≥ 12	≥ 9
<i>Streptococcus faecalis</i> (<i>Sfa</i>) I	GGCC	11	+	10	+
<i>H. influenzae</i> R _d (<i>Hind</i>) II	GTPyPuAC	13	0	1	0
<i>H. parainfluenzae</i> (<i>Hpa</i>) II	CCGG	8	0	13	0
<i>Arthrobacter luteus</i> (<i>Alu</i>) I	AGCT	> 10	0	> 10	0
<i>H. aegyptius</i> (<i>Hae</i>) II	Unknown	≥ 7	0	≥ 6	0
<i>H. influenzae</i> R _d (<i>Hind</i>) III	AAGCTT	0	0	0	0
<i>Escherichia coli</i> R (<i>Eco</i> R) I	GAATTC	0	0	0	0

The enzyme reaction conditions used were those previously reported for each nuclease using duplex DNA as substrate. The number of fragments produced by nuclease digestion of the RF DNAs was taken from refs 3-5 and our results. A + indicates that a number of specific fragments were observed, but the determination of their number was complicated by the presence of exonuclease in the *Sfa*I. The number of fragments generated by *Hpa*II on M13 RF is assumed to be the same as described⁵ for *Hap*II.

Fig. 2 Densitometric scan of *Hae*III fragments of ϕ X174 (+) DNA separated by formamide-polyacrylamide gel electrophoresis. ϕ X174 (+) DNA (3 μ g) was digested with *Hae*III as described in Fig. 1. Sodium acetate was added to the completed digest to 0.3 M, then 2.5 volumes cold ethanol was added. The DNA precipitate obtained after centrifugation was prepared for formamide-polyacrylamide gel electrophoresis as described by Maniatis *et al.*¹³. The DNA was dissolved in 25 μ l deionised formamide, heated at 100 °C for 2 min, then chilled in ice. Following the addition of 5 μ l of 25 mM sodium phosphate (pH 7.5), 75% glycerol and 0.2% bromophenol blue, the DNA sample was layered on a formamide-polyacrylamide cylindrical gel. The polyacrylamide gel (0.6 \times 10 cm) was 4.25% in acrylamide, 0.75% in Bis, and was prepared in 98% deionised formamide with 20 mM sodium phosphate (pH 7.5). Electrophoresis was in 20 mM sodium phosphate (pH 7.5) for 1.75 h at 200 V. The gel was then stained overnight with 0.005% Stain's All in 50% aqueous formamide as described¹⁴. After destaining, the gel was scanned at 560 nm in a Gilford spectrophotometer equipped with a linear transport (—). In a parallel experiment, 2 μ g of ϕ X174 RF DNA was digested with *Hae*III and subjected to formamide-polyacrylamide gel electrophoresis. The peaks of stained RF DNA fragments from a densitometric scan were plotted against the logarithm of the length of the fragments in nucleotides: Z1 (1690), Z2 (1350), Z3 (1025), Z4 (600), Z5 (215), Z6 doublet (175), Z7 (120), Z8 (90), and Z9 (40) (●). The fragment lengths were taken from Middleton *et al.*³. Abscissa is the distance of the DNA fragments from the origin, relative to bromophenol blue. Arrows indicate the *Hae*III fragments of ϕ X174 (+) DNA which do not coelectrophorese with *Hae*III fragments of ϕ X174 RF DNA; no undigested DNA was observed at the origins.

enzyme activity that specifically cleaves RF and (+) strand copurifies throughout the enzyme isolation; 3, three separate *Hae*III preparations in this laboratory cleave both RF and (+) strand DNAs as well as one provided by C. Hutchison, University of North Carolina; 4, the ability to cleave both RF and (+) strand DNAs was lost simultaneously on either dilution or storage at -20°C ; and, 5, *Sfa* I (GGCC) gives products which are virtually identical.

The ability of nine restriction endonucleases to cleave ϕ X174 and M13 DNAs is summarised in Table 1. In addition to *Hae*III and *Sfa*I, *Hha*I (gift of W. S. Reznikoff) also cleaves the (+) strand and RF DNAs. It is not, however, a general capacity of restriction endonucleases to cleave 'single-stranded' DNA since *Hind*III, *Hpa*II, *Alu*I (gifts of I. Nes, M. Mann and H. O. Smith, and L. Maquat and W. S. Reznikoff, respectively) and *Hae*II cut RF DNAs but not the (+) strands. The probability of the 50% G and 50% C containing recognition sites of *Hae*III (GGCC), *Sfa*I (GGCC), *Hha*I (GCGC) and *Hpa*II (CCGG) appearing in any duplex region of the (+) strand should be equal. The failure of *Hpa*II to cleave (+) strand indicates some additional recognition site requirement.

*Hind*III and *Eco*RI (gifts of I. Nes and B. Weissblum, respectively) cut neither the RF nor (+) strand DNAs. Therefore, no new sites for these enzymes are present in the 'single-stranded' DNA which were absent in the RF.

These studies demonstrate that *Hae*III, *Sfa*I and *Hha*I specifically cleave (+) strand DNA apparently because of the

presence of a substantial amount of helical structure in the 'single-stranded' DNA. That ϕ X174 and M13 (+) DNAs are not devoid of ordered structure was indicated in previous studies⁶⁻⁸. Many types of folded structures are possible and all would provide identical fragments for any given enzyme, providing that all potential cleavage sites are in helical regions for each type. DNA structural considerations are not, however, the sole determinant of (+) strand cleavages; enzyme specificity also must be important since *Hae*III, *Sfa*I and *Hha*I digest (+) DNA whereas *Hpa*II gives no cleavages.

DNA breakage caused by dimethyl mercury and its repair in a slime mould, *Physarum polycephalum*

A PRELIMINARY report from our laboratory showed that dimethyl mercury produced a radiomimetic breakage of slime mould DNA and suggested that the damage was repaired enzymatically¹. This communication further characterises the DNA damage and establishes that breakage is independent of DNA replication. It provides conclusive evidence for the existence of a dimethyl mercury repair system and shows that strains of *Physarum* differing in geographical origin have widely different sensitivity to dimethyl mercury damage.

The first set of experiments determined the S value and thus the molecular weight of *Physarum* DNA. Brewer's sucrose gradient techniques² were used, with nuclear isolation media of three different pH values. The observed S value of single-stranded DNA increased with increasing pH in the nuclear isolation medium. At pH 7.5, the calculated molecular weight of single-stranded DNA was comparable with Brewer's value² of 6.3×10^7 . At pH 8.0, 3.77×10^8 was obtained for single-stranded DNA, while at pH 9.0 it was 6.3×10^9 . S values were obtained using the modified Burgi, Hershey relationship³ and molecular weight calculations were based on Studier's⁴ relationship for DNA in alkaline sucrose solutions. As the molecular weight of DNA in each slime mould nucleus is 6.0×10^{11} (ref. 5), and the accepted chromosome number is 50 (ref. 6), the average weight of DNA per chromosome is 1.2×10^{10} . Therefore when nuclei are isolated at pH 9.0 the DNA is recovered as one molecule per chromosome. As the pH of the solution is decreased, the number of DNA molecules per chromosome increases. Bewer *et al.*⁷ suggested a subunit arrangement of single-stranded units in double-stranded molecules (2.3×10^8 daltons) isolated from slime mould nuclei at pH 7.5. Provided that the strain of slime mould used in our study was not fundamentally different in the organisation of DNA molecules in its

nucleus from the strain used earlier, our results suggest that the 'subunit' arrangement is produced by endonuclease which nicks the DNA at pH 7.5, while nuclear isolation at pH 9.0 allows no such nicking.

When *Physarum* was cultured in the presence of $\text{Hg}(\text{CH}_3)_2$ the S value of its DNA decreased considerably, giving a breakage pattern. In some cases it decreased from the normal 150 at pH 8.0, to approximately 10 at pH 8.0. This indicated that there were as many as 10^5 breaks per chromosome.

To find out whether breakage was independent of replication we labelled the DNA with ^3H -thymidine before the addition of the dimethyl mercury. Figure 1 shows that considerable breakage occurred even in the absence of DNA replication. In another series of experiments we found that damage caused by dimethyl mercury was repaired to some extent after removal of mercury by washing the cells once and resuspending them in fresh medium. After two washings followed by resuspension in fresh medium, repair was nearly complete within 24 h.

To obtain conclusive evidence for repair, we used bromodeoxyuridine (BrdU). A culture of *Physarum* was labelled with ^3H -thymidine in the presence of dimethyl mercury. After 24 h of incubation the cells were washed twice and resuspended in a medium containing unlabelled BrdU. (BrdU is incorporated in to DNA in patches where repair takes place, and was suitable for this experiment because it can be photolysed selectively by ultraviolet light (350 nm), allowing the DNA molecules to be rebroken where the original dimethyl mercury breakage and repair occurred.) When the nuclei of BrdU-treated plasmodia were isolated, part of the isolated DNA was exposed to ultraviolet light at 350 nm, while part of it served as a control. Figure 2 shows conclusive evidence that breakage caused by dimethyl mercury is repaired because the photolysed DNA molecules show the typical breakage pattern, while the molecules unexposed to high wavelength ultraviolet light show the unbroken repair pattern.

It is interesting that dimethyl mercury sensitivity varies from strain to strain of *Physarum*. The strain used in our experiments was a local Ontario strain of *P. polycephalum* while a

Fig. 1 Sedimentation of $\text{Hg}(\text{CH}_3)_2$ -treated *Physarum* DNA in an alkaline sucrose gradient. Cultures were treated for 24 h with 9.1 mCi ml^{-1} ^3H -thymidine (60 Ci mmol^{-1} methyl ^3H , New England Nuclear). With this treatment the labelled thymidine in medium is exhausted well before the end of the incubation period. At $t = 24 \text{ h}$ $\text{Hg}(\text{CH}_3)_2\text{OH}$ (0.60 mg ml^{-1}) was added to the medium and incubation continued for a further 24 h. Nuclei were then isolated using extraction buffer, pH 8.0. The nuclei were lysed in 0.5 M EDTA 1.0 N NaOH and 1% SDS. After lysis the nuclei for at least 20 min, the DNA was placed on a $5\text{--}15\%$ linear sucrose gradient and centrifuged for 1.5 h at $20,000 \text{ r.p.m.}$ in the SW25.2 rotor of a Spinco ultracentrifuge. Samples (2 ml) were collected from the bottom of the gradient. Albumin ($30 \mu\text{g}$) was added to each tube and the solutions were acidified and precipitated with trichloroacetic acid. The precipitate was collected on glass fibre filters, dried in glass scintillation vials and 5 ml of Omni-Scint (ICN Chemical and Radioisotopes) was added to each vial. Radioactivity was detected using a Beckman liquid scintillation detector. ●, $\text{Hg}(\text{CH}_3)_2$ -treated; ■, control.

Fig. 2 Evidence for excision repair. Cultures were treated for 24 h in a medium containing ^3H -thymidine ($2.5 \text{ Mi Ci ml}^{-1}$ and $\text{Hg}(\text{CH}_3)_2$. The cultures were washed twice (using low-speed centrifugation) and placed in medium containing BrdU ($20 \mu\text{g ml}^{-1}$), fluorodeoxyuridine ($5 \mu\text{g ml}^{-1}$) and Uridine ($20 \mu\text{g ml}^{-1}$). The cultures were then incubated for a further 24 h. Nuclei were isolated and lysed as described for Fig. 1. Samples (6 ml) of lysate were irradiated in open glass 10-cm Petri dishes for 30 min (350 nm , $26 \mu\text{W cm}^{-2} \times 100$) using a Gelman ultraviolet lamp. Irradiated lysates and unirradiated repaired lysates were analysed in the alkaline sucrose gradient as for Fig. 1. ●, Ultraviolet, (350 nm) irradiated; ■, non-irradiated.

strain of *Physarum* (M_3C) cultured originally at the McArdle Laboratory for Cancer Research in Madison, showed considerable resistance to the effects of dimethyl mercury. Even when the amount of dimethyl mercury present during treatment was double that used in the previous experiments, M_3C showed little or no DNA breakage. If comparable variations in sensitivity to dimethyl mercury-induced DNA damage exist in mammalian populations, the establishment of safe limits of dimethyl mercury in the environment is a more complex problem than might previously have been believed.

Corrections in the catalogue of oligonucleotides produced by digestion of *Escherichia coli* 16S rRNA with T_1 RNase

SINCE its initial publication¹, the catalogue of oligonucleotides generated by T_1 RNase digestion of *Escherichia coli* 16S RNA has undergone a number of revisions and refinements²⁻⁵. At present the literature contains two rather dissimilar documented versions of this catalogue^{2,3} and disagreements hold for 50% of sequences octamer and larger³. Confusion is not relieved by recent publications concerning the 16S rRNA primary structure^{6,7} that now incorporate some of the oligomer sequences of Uchida *et al.*³ but reject others, without resort to new evidence, however.

The situation demands definitive resolution. The uncertainties regarding oligomer sequences must be settled before one can use comparative approaches to the 16S rRNA sequence and before the ultimate goal of this research, the detailed molecular analysis of ribosome structure and its relationship to function,

can be approached. Therefore, we here review all (T_1) oligomer sequences from the *E. coli* 16S rRNA catalogue for which there has been controversy or uncertainty.

All uncertainties in sequences are herein resolved (with the exception of two post-transcriptionally modified oligomers) due in part to the additional sequence information provided by a new endonucleolytic procedure (unpublished results of M. Sogin, D. S., L. Bonen and C. W.).

All relevant procedures—for generation of oligomers, their separation by two-dimensional electrophoresis, and for their sequence determination—are published in detail elsewhere³. Briefly, in determining individual oligomer sequences, we have used three types of (secondary and tertiary) endonuclease cleavages: (a) pancreatic (specificity for pyrimidines); (b) U2

(preferential cleavage of purines, cleavage of pyrimidines also under more stringent conditions³), and (c) the new activity, T3 (a complex, and so, useful specificity, outlined in Table 1). In almost every instance, a sufficient variety of fragments of an oligomer is generated by these methods to enable a sequence deduced from one subset of fragments to be confirmed by another.

Table 1 presents the correct sequences (and the incorrect versions they replace) for all the oligomers in question. Crucial secondary digestion products used to establish sequence in each case are shown, as are digestion products not found which, by their absence, disprove the incorrect versions.

It has been suggested that many of the differences between the two documented versions of the 16S rRNA catalogue reflect

Correct sequence for the (T₁ nuclease) oligomers in the *E. coli* 16S rRNA catalogue, the sequences of which had previously been disputed, ambiguous or uncertain. ³²P-labelled 16S rRNA isolated from 30S ribosomal subunits of *E. coli* B236 was digested with T₁ RNase and the digest fingerprinted by the two-dimensional electrophoretic procedure of Sanger and co-workers^{3,8}. The first (cellulose acetate) dimension was run in 0.003 M EDTA containing 7 M urea and brought to pH 3.5 with acetic acid; the second dimension (on DEAE cellulose) in 0.1 M pyridinium formate was brought to pH 2.3 with formic acid (unpublished results of M. Sogin, D. S., L. Bonen and C. W.). Individual oligomer spots, located by autoradiography, were sequenced by secondary and tertiary endonucleolytic procedures involving (1) pancreatic nuclease, (2) U2 nuclease, and (3) T3 nuclease activities³. The details of this last procedure will be published elsewhere, but in that it is novel, the procedure will be described briefly here. T3 activity is used chiefly in characterising pyrimidine stretches; it cleaves (T₁) oligomers most readily at U residues, and most slowly at C residues. Thus, for example, the six isomers of (C₂U₂)A would yield the following products, dominant products being overlined: (1) CCUUA → CCUU, CCU, CUU, CUA; (2) CUCUA → CU, CUA, CUCU, (3) CUUCA → CUU, CA, CU; (4) UCCUA → U, CCU, CCUA, CUA, CU, A; (5) UCUCA → U, CU, CA, CUCA; (6) UUCCA → UU, CCA, U, CA. Each correct oligomer sequence (column A) is paired with the incorrect or uncertain versions thereof which have appeared in published versions of the 16S rRNA sequence^{5,6}. The former are assigned numbers designating their relative position in the 16S rRNA sequence^{6,9}; the latter, where appropriate, are given their number designations assigned by Fellner *et al.*³ (*), (**), and (***) indicate respectively that an oligomer of that sequence is found in some other Enterobacteriaceae, most other Enterobacteriaceae, and in over 85% of prokaryotic 16S rRNAs screened^{9,10}. Secondary pancreatic nuclease digestion products, which are in all cases obvious, and concerning which no substantial disagreement exists, are not shown. The important secondary U2 and T3 nuclease digestion products in each case are shown in columns B and C respectively. Their sequences, where necessary, have been proven by further analysis. Column D lists digestion products predicted by the incorrect sequences, but not found. A dot placed over a nucleotide indicates that it has been post-transcriptionally modified. (Superscripts 3 and 7 indicate sequences reported in the corresponding references.)

*This sequence is tentative. Nevertheless, we feel that our data are inconsistent with the projected sequence of Fellner¹³ for these reasons: pancreatic nuclease products are a G, a C, and a spot containing two phosphates, that must be a dimer also by virtue of its electrophoretic mobility on DEAE cellulose in 0.1 M pyridinium acetate, pH 3.5 (PA) buffer; also the dimer must carry positive charge in that it runs faster than AC or CA, (but slower than the slowest monomer, G). T3 cleavage releases the same dimer (it is not cleaved further by pancreatic nuclease) and CG as the major products. For these reasons plus its position on the primary fingerprint³, we believe oligomer No. 75 to be a tetramer, of the form XCCG, where X could be the modified nucleotide previously identified¹³.

†We have detected C₄UG, C₅UG and so on and C₆U, C₄U and so on under conditions where C₆UG or C₆U, had they been present, would have been clearly recognised.

‡ACCCG does not exist in the *E. coli* strain we characterised fully³. But we cannot rule out the possibility that this represents a strain difference. §ACAUCCACG was not reported by us previously³. It appears to have been overlooked, as a minor contaminant in a cluster containing three other oligomers. This sequence has not been seen in other enterobacteria, but the closely related one, ACAUCCAG, occurs in three of the five enterobacteria so far screened¹⁰.

¶We previously reported CCCCU... in this oligomer³, based not on definitive tertiary analysis, but position on the primary fingerprint. T3 digestion proves CCCU and CCCUU to be the largest possible pyrimidine stretches in the sequence.

"We are not certain of the nature, position, and number of the modifications here. We tentatively conclude a sequence C[•]CCG, but cannot rule out the alternative, that is two modified bases, proposed by Fellner¹³.

**In the catalogue of Uchida *et al.*³, the sequence of this 3'-terminal segment had been narrowed to the two possibilities shown. The sequence has also been determined by several other laboratories¹⁴⁻¹⁶.

††Fellner *et al.*³ and Ehresmann *et al.*⁶ report (and place in sequence) four copies of CCUG but no copies of CUCG. Uchida *et al.* found two copies of CUCG and three copies of CCUG in the *E. coli* 16S rRNA catalogue³. We feel this does not represent strain difference. All five enterics screened contain at least one (most contain two) copies of CUCG and three or less copies of CCUG.

strain differences. This explanation we reject in all or almost all instances. Not only are all the oligomers hexamer and larger we report found in both B and K strains of *E. coli*³, but most of them are found in some (*in Table 1) or most (**) of the other Enterobacteriaceae screened, that is *Aerobacter*, *Yersinia*, *Proteus* and *Serratia*, and many of these in at least 85% of all other prokaryotes screened (***) as well⁹⁻¹².

It should be recognised that the oligomer sequence corrections made here do not bring into question the projected 16S rRNA sequence, unless the correction would change the composition of one of the pancreatic nuclease oligomers that overlap a given (T₁ nuclease) oligomer. At present no oligomers for which this latter condition holds are placed unequivocally in the 16S rRNA sequence⁶.

The work was supported by a grant to C. W. from the National Institutes of Health.

Note added in proof: Yuki and Brimacombe have recently published¹⁷ evidence inconsistent with three sequences (Nos 143, 165, 175) above, but consistent with the alternative versions we reject. These discrepancies could all reflect errors in interpretation of certain mobilities in the pH 3.5

system, together in one case (No. 143) with 'overcutting' by ribonuclease U2. Specifically, confusion of UUA with CUG (No. 165), UA with CG (also No. 165) and in CUA with CCG (in No. 175) are possible. If this last explanation is correct, it necessitates the interchanging of the oligomers No. 175 (CUACACACG) and No. 203 (UACACACCG) in the 16S rRNA sequence.

Radioiodine escape is an unexpected source of radioimmunoassay error and chronic low level environmental contamination

PROTEINS and peptides^{1,2} labelled with radioactive iodine (¹²⁵I or ¹³¹I) are commonly used in radioimmunoassays and other investigative procedures. Although decomposition of such labelled molecules can liberate iodide (I⁻) ions^{3,4}, which remain in solution, liberation of elemental radioactive iodine (I₂) has not been reported, as far as we know. Our findings reported here imply that, in conditions common in many radioimmunoassay laboratories, appreciable quantities of gaseous radioactive iodine can indeed escape from radioimmunoassay tubes.

While recounting several radioimmunoassays after a gamma-counter breakdown, we noted an unexpectedly rapid decline of radioactivity in the T tubes (capped 12×75 mm culture tubes containing only 100 µl of the ¹²⁵I-labelled protein antigen solution) which were being used to assess total radioactivity⁵. Because comparable decay was not seen in the other assay tubes, apparent "percentage-binding"^{4,6} seemed to increase progressively. The expected rate of isotopic decay (about 1% per day) was seen with tubes containing only inorganic ¹²⁵I solution, which seemed to rule out isotopic impurity as an explanation.

The possibility that the phenomenon was due to physical migration of isotope was investigated by serial gamma camera scintillography of two specially prepared T tubes. The gamma images (Fig. 1a-c) revealed progressive displacement of isotope from the solutions at the bottoms of the tubes to the tops. The central sections of the tubes remained devoid of detectable radioactivity. During this experiment, total radiation flux remained essentially constant, suggesting that the Parafilm caps had retained the iodine within the tubes, at least during the 2.5 h of observation. Of course, the material at the tops of the tubes would have been virtually undetectable during well-type gamma counting.

To determine whether the losses from the bottoms of such tubes would continue to equal the gains at the tops, several

ordinary T tubes which had already displayed count rate decays of 25% or more were rapidly frozen (to immobilise the solution) and cut in two. The bottoms and tops (inverted) were then counted separately. The count rate for each bottom was essentially the same as for the intact tube. The rates for the tops were significant (2×10^3 - 4×10^3 c.p.m.) but very much less than the missing radioactivity (about 3×10^4 c.p.m.). This finding, together with the apparent absence of radioactivity in the midsections of such tubes (Fig. 1c), implied that a major part of the translocated radioactivity was gaseous (presumably I₂) and had therefore escaped when the tubes were cut. That some of it had escaped even before the tubes were cut became evident when the shield tubes, in which these Parafilm-capped T tubes had been counted initially, also displayed significant radioactive contamination (again, not enough to account for the missing radioactivity).

These initial observations involved a very heavily iodinated preparation of labelled rat follicle stimulating hormone (FSH) (Table 1, line 1), but similar disappearance of radioactivity has been seen with much less strongly iodinated preparations of several pituitary hormones (Table 2). Table 1 contrasts the rapid apparent count rate decays for T tubes with the relatively slower decays displayed by tubes containing (1) various additives in solution; (2) precipitated trace-antibody complex (0-tubes), and (3) a sample of inorganic ¹²⁵I. With each of these labelled hormone preparations, the apparent rate of decay was minimal during storage at 4 °C in screw-cap jars but increased markedly when small volumes (100 µl) were placed in Parafilm-capped culture tubes and kept at room temperature. Accidental or deliberate puncturing of the caps further accelerated the apparent decay rate.

The trace preparations shown in Tables 1 and 2 were all iodinated essentially as described by Midgley⁵, using 0.125-0.75 mCi of ¹²⁵I per µg protein, 15-30 µg of chloramine-T, 60-175 µg of sodium metabisulphite and a reaction time of 40-128 s. About 150 mg of stable potassium iodide was used in the transfer solution. All had been purified by separating iodinated protein from fragments and free iodide, using gel columns (Biogel P-60) pretreated with either 5% ovalbumin or 0.2% gelatin. All had been immediately diluted to working strength in phosphate-buffered saline, pH 7.0, using 0.1% gelatin as the carrier protein.

The use of gelatin, which contains little tyrosine, as an alternative to 0.1% albumin (1% liquid egg white) had been adopted only recently⁷. Before second antibody precipitation, the assay tubes containing precipitates had held larger volumes of 0.1% gelatin solution than the T tubes (500 µl compared

The distinctly overiodinated preparations (initially about 2.38 and 1.63 atoms ¹²⁵I per molecule, respectively) were prepared on February 28 and March 18, 1975 and, except for the 0 tubes and metabisulphite experiment, studied concurrently. Effects of adding EW, G and S were similar with both preparations. The rat FSH (rFSH), and the rat LH, TSH and prolactin (rLH, rTSH and rProl) shown in Table 2, were gifts from the NIAMD rat pituitary hormone distribution program. EW, egg white; G, gelatin; S, starch; M, metabisulphite.

*Expressed as µCi in protein peak per µg protein iodinated.

†All counts are in hundreds, that is, 1,379 = 137,900 c.p.m. Each datum (except for 0 tubes) is the mean of duplicate tubes.

‡Note complete prevention of ¹²⁵I escape during 11 d at room temperature.

with 100 μl) as well as other proteins (immune and non-immune sera) not present in the T tubes. Table 1 shows that the presence of protein solution (even gelatin, in adequate volume) can retard, or even totally prevent, radioiodine escape.

A complete explanation of this phenomenon is beyond the scope of this report. There are two possibilities. One is that iodine can be released from covalent bonding to tyrosine residues as a result of radiation damage³. The other is that it is released from non-covalent radioiodine-protein bonds. It is known (Fig. 8b and c of Yalow and Berson³) that free radioiodide does appear on storage of ^{125}I -labelled protein preparations. This radioiodide may be converted, at least in part, to radioiodine. The facts that (1) escape of radioiodine accelerates when trace solutions are brought to room temperature and exposed to air, and (2) addition of metabisulphite can partially prevent this escape (Table 1) suggest that some type of chemical oxidation is involved.

Escape of radioiodine poses two sets of problems. The most immediate is the potential hazard to laboratory personnel who may be undergoing chronic, low level exposure to an environment contaminated with radioiodine. The extent of this hazard would be expected to vary widely, because of variations in rates of trace protein decomposition (Tables 1 and 2) and amounts of radioiodine-labelled protein subjected simultaneously to destabilising conditions. Thyroid scans of the four individuals who would have received the greatest exposure during the 2-month period throughout which ^{125}I had been escaping in our laboratory (that is before the institution of the precautions discussed below) revealed no detectable

neck radioactivity (less than 0.05 μCi). Conditions during this short period (moderate numbers of assay tubes, high rate of air exchange) did not favour maximum environmental contamination. We have, however, calculated that laboratory conditions could exist in which air concentrations of radioiodine escaping from assay tubes could exceed US Nuclear Regulatory Commission air concentration limits (10 CFR 20, Appendix B) by as much as 500 times. (To reach these extreme limits, large numbers of assay tubes would have to be kept at room temperature in a small space with a poor rate of air exchange. Nevertheless, since this report was prepared, we have learned of one laboratory in which detectable neck radioactivity was encountered in a technician who worked in a room in which discarded assay tubes were stored.)

Radioiodine escape, at any rate, is clearly undesirable⁸, particularly with ^{125}I (half life 60 d). Allowing it to occur unchecked now seems inexcusable, since it can be minimised by the following simple precautions: adding a tyrosine-rich carrier protein (such as albumin) to the solution in which trace is stored; keeping stored solutions tightly capped and cold; adding a sufficient volume of albumin solution to all assay tubes. In the important case of the predominant assay tubes, those containing antigen-antibody precipitate, the small but distinct decay due to iodine escape during storage at room temperature (0-tubes in Table 1) can be blocked for at least 21 d by covering the precipitates with 500 μl of 1% albumin solution immediately after decanting the supernatant. (This innovation has noticeably improved assay precision in our laboratory). These precautions, however, would not be expected to prevent protein-radioiodine dissociation, but only to conceal its development by trapping the isotope in solution, as ^{125}I -labelled albumin. Progressive distortion of measurements of antigen-antibody interaction^{4,6} would still result. Nonspecific labelling and/or label lability could also complicate tissue localisation studies⁹.

We thank Jean M. Jungman for technical assistance, Ajay S. Bhatnagar for valuable theoretical suggestions, and the National Institutes of Health for financial support.

Fig. 1 Successive gamma camera images of two Parafilm-sealed (12×75 mm) culture tubes containing ^{125}I -labelled rat FSH solution, showing progressive saltatory displacement of ^{125}I from solution. Times: (a) 15-35; (b) 75-95; (c) 135-155 min after preparation. The gamma camera was a Searle Pho-Gamma HP coupled to an Intertechnique Cine 200 Data Collection System. Each tube contained 0.1 ml of a concentrated solution of the ^{125}I -labelled FSH shown on line 1, Table 1, and was sealed with three or four layers of Parafilm. About 15 min after preparation, the tubes were mounted upright in the field of the (pinhole-columnated) gamma camera. Although they were not moved during the series of 20 min exposures, the tube on the right had been shaken manually (before mounting) to simulate travel in an automatic gamma counter. This seemed to accelerate subsequent volatilisation of radioactivity. The use of concentrated solution was dictated by gamma camera availability. Similar pictures of ordinary T tubes would have required longer exposure periods.

Erratum

In the article "Methyl group as a probe of chirality in Raman optical activity" (*Nature*, **255**, 458; 1975) the author's name should be L. D. Barron and not as printed. Parts of the figures in the original article could not be seen clearly so they are reprinted below on a larger scale.

Fig. 1 The depolarised Raman circular intensity sum (top) and difference (centre) spectra, as recorded, of methyl asymmetric deformations in: *a*, (+)- α -phenylethylamine; *b*, (-)- α -phenylethylamine; *c*, (+)- α -phenylethanol. At the bottom is a sum spectrum at high resolution. Instrumental conditions: laser wavelength 4,880 Å, laser power 1 W, slit width 1,500 μ m for the top and centre spectra and 200 μ m for the bottom spectra. The absolute configurations are taken from ref. 10.

Fig. 2 The depolarised Raman circular intensity sum and difference spectra of methyl torsions in: *a*, (+)-3-methylcyclohexanone; *b*, (+)-3-methylcyclopentanone; *c*, (+)-carvone; *d*, (-)-limonene; *e*, a saturated solution of (+)-dimethyldibenz-1,3-cycloheptadiene-6-one in acetone. Instrumental conditions as for the top two spectra in Fig. 1, except that a laser wavelength of 5,145 Å was used in *e* to minimise fluorescence.

reviews

THIS volume* contains 18 papers presented in 1972 at a conference attended by scientists, historians and philosophers at the Villa Serbelloni in Bellagio, Italy. Each paper is followed by comments of one or more of the participants, usually Bernard Rensch. If the subject of this conference was, as Ledyard Stebbins (p. 285) claims, reduction in biology, then few of the participants addressed themselves to the issue.

The two boundaries between natural phenomena which are of greatest interest in arguments over reduction are that between the mind and physiological processes and that between biological processes in general and the subject matter of physics and chemistry. Until quite recently, all of the carefully worked out examples of reduction have concerned reduction within physics, the reduction of one physical theory to another. Thus, the next step would seem to be the analysis of similar examples within biology. Furthermore, these are exactly the examples that professional biologists are best prepared to deal with constructively. But the topic never arose. Instead, most of the papers which touched on reduction at all, dealt with the reduction of mind to physiological processes and a few concerned the reduction of biological processes to physics and chemistry.

The papers divide fairly naturally into three groups: historical, biological, and philosophical. The philosophical papers divide somewhat less easily into those which are straightforward philosophy and those which are 'philosophical' in the pejorative sense. The papers by Ernest Boesinger, June Goodfield, and G. Montalenti are primarily historical. Boesinger traces the fate of the evolutionary hypothesis after Lamarck and Darwin, giving special attention to the bizarre situation which still prevails in France. Goodfield attempts to derive some conclusions about reductive strategies by studying the methods and results of a variety of biologists in the 19th and 20th centuries. Montalenti compares mechanistic reductionism and holistic vitalism in Democritus, Aristotle, and Darwin. Gerald Edelman's paper is also historical, discussing as he does the recent history of the theory of clonal

Philosophy of reductionism in biology

Aristotle—mechanistic reductionism and holistic vitalism. Taken from Hartmann Schedel Liber Chronicarum (Nuremberg Chronicle), Nurnberg, 1493.

selection in antibody formation. The papers by Dobzhansky, Stebbins and John C. Eccles are mainly biological. If there was ever an excuse for the ill-informed parodies that so often pass for discussions of the synthetic theory of evolution, Dobzhansky's lucid synopsis eliminates it once and for all.

The papers by Morton Beckner, Dudley Shapere, Francisco Ayala, Donald Campbell, and Karl Popper are truly philosophical. Beckner exploits the distinction between hierarchically arranged theories and hierarchically organised natural systems. Shapere expands upon the difference between compositional and evolutionary theories and the different sorts of problems which give rise to them. Donald Campbell sets out his views on evolutionary epistemology, views shared in part by Popper and Henryk Skolimowski. Just as biological species adapt to their changing environments by a process of variation and selective retention, individual organisms come to learn about their environments and successive scientific theories come to characterise the real world with ever increasing accuracy. One problem with this

philosophical thesis concerns the appropriate adjective required to modify the term 'variation'. In what sense are mutations 'chance'? In what sense is learning and the development of science 'blind'?

Ayala presents a surprisingly informative and sensitive linguistic analysis of "evolutionary progress", surprising because such analyses are rarely informative and even more rarely produced by practicing scientists. Stebbins also deals with the notion of progress in his contribution. Peter Medawar presents an uncontroversial comparison between levels of generality in geometry and the natural sciences. Skolimowski, on the other hand, presents an unnecessarily petulant attack on the conventional notion of rationality in science. The tone of Skolimowski's paper is especially unfortunate because the issues are both important and inherently liable to distortion and caricature.

Large chunks of the papers by Rensch, Eccles, W. H. Thorpe, and Charles Birch exemplify what can happen when a noted scientist tries his hand at 'philosophising': these papers are uncomfortable reading. The biology is accurate and often inherently fascinating—for example, Eccles' discussion of split brain experiments and Thorpe's description of migration and exploratory learning—but too often their attempts to set out philosophical theses are as embarrassing as the efforts of an ageing *diva* trying to sing the latest pop song. Although Shapere values interdisciplinary endeavours, he replies to these poorly formulated views in the only way a professional philosopher can (pp. 256, 258). Just as scientists are entitled to establish standards of competence for their undertakings, philosophers have a right to expect at least minimal competence in theirs.

I have, however, saved the best part of the book until last. Monod did not present a formal paper at the conference; instead, he defended his book *Chance and Necessity*. The ensuing discussion points up, in the most direct manner possible, both the obscurity and importance of the problems which surround the issue of reduction. Several of the papers in this volume go a little way towards reducing the obscurity, and the emotional exchange between Monod and Skolimowski attests to the importance of these issues. I could not recommend that anyone read this volume cover to cover, but a few of the papers are worthwhile and the final 20 pages, in which the participants quiz Monod, should not be missed.

David L. Hull

**Studies in the Philosophy of Biology: Reduction and Related Problems*. Edited by Francisco J. Ayala and Theodosius Dobzhansky. Pp xix+390. (Macmillan: London and Basingstoke, September 1974.) £12.00.

THIS volume* is the result of a gathering in April 1974 of scientists from different disciplines with a common interest in the thymus. Fifty-three contributions on various aspects of the thymus unfortunately make heavy reading and because they are all formal papers it is difficult to measure the success of the meeting in providing a forum for the exchange of ideas. Rarely does one find proceedings that do justice to the tone and atmosphere of a meeting.

Although all immunologists have believed in the importance of the thymus, most in the past have paid only lip-service to the notion that thymocytes and T cells exert their influence through soluble factors. In the last four years, however, this has changed and now everybody is chasing factors. The inevitable result has been an explosion in the literature and a proliferation of factors which reflects more the individuality of the scientists than the molecular nature of the factors themselves. To a certain extent this book provides an opportunity to compare the many different approaches of the workers in the field, but this could have been made easier by a more extensive editorial summary.

The volume is divided into six sections, by far the most readable of which are the first (the T cell story) and the last (perspectives of the role of thymus factors in immunity), which can be recommended to any reader. The filling of this sandwich comprises sections on soluble factors and T cell development, the preparation of thymic factors, their activity *in vitro* and their activity *in vivo*. The articles are generally well presented and illustrated but many of course have been superseded in the year it has taken to publish this work. This is a universal fault with conference proceedings and it is a shame that it has happened in this case because this is a very useful reference work. Although it contains much on thymic hormones, it has little to say about the functioning of immune responsiveness genes—which is a pity as this is a fascinating and rapidly expanding area.

What the volume does achieve is to highlight the lack of standardisation of thymic factors. One may hope that an attempt to achieve agreement in this area will arise out of meetings such as this. Another salutary achievement is

Role of the thymus in immunobiology

Diagram of the six chakras in the subtle body, Kangra, Himachel Pradesh. Gouache on paper, eighteenth century. "The first and fundamental image which reflects inner facts is the 'subtle body', which is shared by all Indian traditions, as well as by Indian medicine. It is experienced as that immense ramification of channels of energy which flows through the entire body." Taken from *The Body as a Medium of Expression* edited by Jonathan Benthall and Ted Polhemus. Pp. viii + 333. (Allen Lane, Penguin Books: London, May 1975.) Hardcover £7.00; paper £3.50.

in the underlying current of caution expressed in interpreting cellular function by the presence or absence of differentiation antigens on cells exposed to thymus factors.

Norman A. Staines

SINCE the discovery in 1968 of genetic athymia in 'nude' (*nu/nu*) mice, the continuing study of these animals is throwing new light on the functions of the mammalian thymus. About 200 papers have been published so far, and an analysis of the present state of the subject would obviously be very useful.

Dr Rygaard's book† does not satisfy this need adequately. It was, in fact, published in Denmark in 1973 and is now being marketed more widely, without change or addition. Unavoidably, in a fast moving field it is already out of date. Suffice it to say that the majority of research reports on the nude mouse belong to the period after the book was written. Furthermore, out of 83 papers known to me from the period up until the end of 1972, 34 are not listed in the references.

A quarter of the book is devoted to the author's own line of experimentation—demonstrating that the athymic animal accepts grafts from a variety of vertebrate species. Data of body and organ weights of nude and control mice are presented in convenient tables. Rather unexpectedly, spleen and lymph node weights were usually higher in nude mice than in normal controls. The levels of various serum proteins, including gamma globulins, were also normal. The problems raised by some of these data are pointed out but not followed up.

The coverage of other topics is rather uneven and cursory. No tables, graphs or illustrations from other workers' original reports are incorporated. Work on the production of humoral antibodies is summarised rather too briefly.

The last two chapters are based on the author's own finding that no spontaneous tumours developed in any of over 11,000 nude mice recorded. He rightly points out that the short life span of these animals permitted an average observation time of only 4 months, but proceeds to deemphasise this difficulty on grounds that are not altogether decisive. The statement, for example, that auto-antibody production is rare in nudes can be questioned. Essentially, on these bases, the author expresses doubts about the theory of immunological surveillance and declares his conversion to the ranks of agnostics in this respect.

The book is written in a lively style and is attractively produced. In spite of its limitations, it is likely to stimulate interest in the study, through the nude mouse mutation, of the thymus. E. M. Pantelouris

**Thymus Factors in Immunity*. (Annals of the New York Academy of Science, Vol. 249.) Edited by Herman Friedman. Pp. 547. (New York Academy of Sciences, February 1975.) \$39.00.

Corrigendum. In the review of *Registry of Mass Spectral Data: Volumes 1-4* (*Nature*, 257, September 4, 75, 1975), the collective price of the four volumes was incorrectly stated as £250.00. The price should have read £155.25.

†*Thymus and Self: Immunobiology of the Mouse Mutant Nude*. By Jørgen Rygaard. Pp. 193. (Wiley-Interscience: London and New York, March 1975.) £6.50.

Mechanics of Polymers. By R. G. C. Arridge. Pp. ix+246. (Clarendon: Oxford; Oxford University: London, June 1975.) £6.50.

Books on the mechanical properties of polymers range between two extremes: the practical approach is to present large quantities of data held together with theoretical interludes, whereas the pure approach is to stick mainly to theory and only introduce data occasionally.

This book is predominantly of the second sort. There is a thorough discussion of elasticity theory, including large strain elasticity and anisotropy, and a chapter on time-dependent elasticity theory, but these are left hanging as the chapter on applications to polymers discusses mainly transition temperatures and test methods.

The treatments of anisotropy and of yield and fracture are more integrated, although there are relatively few examples. The discussion of fracture is very short.

This book is too uneven to be a good general text, although individual chapters may prove valuable. Most of the material is also in Ward's *Mechanical Properties of Solid Polymers* (1971). An understanding of vectors and tensors is required. Most of the time SI units are used. Some of the diagrams, particularly of chemical structures, are unclear.

P. D. Calvert

Applications of High-speed Liquid Chromatography. By J. N. Done, J. H. Knox and J. Loheac. Pp. vii+238. (Wiley-Interscience: London and New York, January 1975.) £6.50.

THE technique of high speed, high pressure, liquid chromatography (HPLC) is one of the more rapidly expanding areas of analytical chemistry: it now rivals gas chromatography in terms of practical importance. The primary advantage of the method is that it can separate compounds which are not readily amenable to gas chromatography; for example, polymers, high molecular weight compounds, and ionic and strongly polar species such as steroids and sugars, and so on.

In the modern analytical laboratory any decision to invest in a new technique is often dependent on an assurance that it can solve a specific problem. This book aims to assist in this decision and also to provide a much needed practical guide to the field.

After a brief but effective coverage of the technique and theory of high speed liquid chromatography the major section of the book consists of examples of selected chromatograms taken from the recent literature. The 150 examples

shown illustrate the wide range of compound types amenable to HPLC and cover hydrocarbons and petroleum, acids, amines and nitrogen compounds, phenols and antioxidants, sulphonic acids and dyestuffs, insecticides and herbicides, nucleotides and nucleic acid bases, pharmaceuticals, steroids and natural products. Each chromatogram includes details of column material, column length, packing and particle size, operating temperature, pressure type of detection and sensitivity.

As the authors correctly point out, the rapid advances in this field will lead to improvement in some of the chromatograms but the operating conditions will not undergo any radical changes.

Altogether this is an excellent book, concise and well documented and providing the essential information for anyone contemplating the use of this important technique.

B. Fleet

Books brief

Compaction of Coarse-grained Sediments, (Developments in Sedimentology 18A.) Edited by George V. Chilingarian and Karl H. Wolf. Pp. 552. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl. 130; \$54.25.

THIS latest contribution to the series *Developments in Sedimentology* is the first of a two-volume appraisal of compaction of coarse-grained sediments, and complements an earlier volume dealing similarly with argillaceous sediments. For such a highly specialised subject, embracing so many disciplines, the editors have succeeded in assembling a balanced collection of well presented and illustrated papers which should largely satisfy geologists and engineers working in this field. Most of the chapters are essentially of a review nature and contain comprehensive bibliographies; as such, the book should serve as an invaluable source of reference.

Of specific interest to geomechanics are chapters dealing with experimentation and mechanics of sand compaction (Allen and Chilingarian), its effects on such properties as sediment porosity, permeability, strength and so on (Ingles and Grant), and a detailed presentation of mathematical models illustrating problems arising from the compaction of porous solids (Raghavan and Miller).

Sedimentologists are catered for in papers dealing with compaction of carbonate sands (Coogan and Manus), a case study demonstrating how

differential sand-mud compaction can determine the geometry and distribution of elongate sandstone bodies (Brown) and the use of geophysical well logs in recognising depositional environments and sediment compaction (Allen). Bissell and Chilingarian review the magnitude and possible causes of hypersubside in various sedimentary basins in North America as well as reporting on localised subsidence related to oil and water extraction.

The second part is eagerly awaited.

Brian Waugh

Chemical Oceanography. Edited by J. P. Riley and G. Skirrow. Volume 1. Pp. xx+606. £18.50; \$49.00. Volume 2. Pp. xx+647. £19.50; \$51.50. (Academic: London and New York, June 1975.)

THIS edition up-dates the previous one of about a decade ago and these volumes benefit from more quantitative descriptions of marine chemical phenomena. Refreshingly, an attempt has been made to standardise units of measurement throughout these volumes. Most of the chapters contain a complete range from basic theory to modern applications in the field. An excellent example is the chapter on seawater as an electrolytic solution, in which well-developed arguments are used to explain its complex electrolytic nature. The overview that this and some other chapters present is the most significant improvement on the earlier edition—frequently a catalogue of random measurements of chemical species.

The impression that chemical oceanography lags some way behind other fields of science is dispelled by many of the chapters. Others only confirm this impression—for example, the essay on micronutrient elements comprises much work completed twenty years and more ago. The chapter on dissolved organic material in seawater confirmed the unsatisfactory state of research in this area. The all-embracing expression 'dissolved organic matter (DOM)' appeared too often and is of limited usefulness. The inclusion of DDT and PCB seemed out of place, and I was not convinced as to the accuracy or completeness of the information presented on chlorinated hydrocarbons.

The opportunities for criticism in these volumes were few. The books taken as a whole provide a comprehensive picture of chemical oceanography today. To anyone interested in the marine environment I warmly recommend this major work.

M. M. Rhead

obituary

William Marshall Smart, FRSE, FRAS, Regius Professor of Astronomy in the University of Glasgow from 1937–59, died on September 17 at the age of 86.

Professor Smart was born in Scotland and gained his MA at Glasgow in mathematics and natural philosophy in 1910 and his BSc in 1911. He was awarded a scholarship to Trinity College, Cambridge, where he read for the mathematical tripos. After World War I, which he spent in the Royal Navy, he returned to Cambridge as John Couch Adams Astronomer and Lecturer in Mathematics. He was the author of several popular books on astronomy (*The Sun, The Stars and the Universe*, 1928, *Stellar Dynamics*, 1938, and *Some Famous Stars*, 1950) and also published textbooks on the mathematical theory of astronomy. During World War II, he returned to the problems of navigation, publishing

several books which were to play a significant role in the training of navigators in the Navy and Air Force. He was President of the Royal Astronomical Society and a Vice-President of the Royal Society of Edinburgh.

Marshall Kay, Newberry Professor Emeritus of Geology at Columbia University, died on September 3 in New Jersey at the age of 70.

Born in Ontario, Dr Kay gained his first degree in 1924 at the University of Iowa and his PhD at Columbia in 1929. He joined the geology faculty as a lecturer and became assistant professor in 1937, an associate professor in 1941 and a full professor in 1944. In 1967, he became the sixth Newberry Professor of Geology. Dr Kay paved the way for new global tectonics with

his pioneering modern continental drift theory. His theories from reconstructions of continental movements, demonstrating that North America's boundaries were delineated 400 Myr ago when upheavals in the ocean floor consolidated offshore chains of volcanic islands with the mainland, supplanted earlier theories of the origin on the North American continent. Dr Kay suggested that on the basis of his theory of expanding continents, Japan would eventually merge with the Asian mainland. The theory also envisages Alaska again becoming part of Siberia and that the China Sea would 'disappear' into South Asia. "For profoundly influencing the theory and practice of modern stratigraphy", the Geological Society of America presented him with the Penrose Medal. He was also awarded the Kunz Prize by the New York Academy of Sciences.

Postgraduate education: MITs in Britain?

ON the same day that the Science Research Council (SRC) was launching its annual report (bearing, predictably, little good news for the practitioners of 'big science') it was also publishing a much less predictable document that makes some very radical suggestions. *Postgraduate Training* (SRC, free) should be read by every postgraduate, every academic and every industrialist in the business of hiring university-educated people.

A year and a half ago, the Commons Expenditure Committee looked at the postgraduate training scene in Britain across a spectrum from student funding to national relevance. It took advice from a strangely limited range of witnesses and came up with a dim view of the utility of higher degrees. The Department of Education and Science has been slow to reply to the criticism; in a sense this report can be seen as an attempt to remedy that deficiency. In no way, however, is it a stonewall defence of the *status quo*. The SRC working party, chaired by Sir Sam Edwards, has instead taken upon itself to inject ideas for change into the debate, and to propose major reorganisation at the postgraduate level.

The guiding principle behind the report is that postgraduate education should become less of a training ground for research workers and more of a broad continuation of the educational process. Several reasons are advanced. One is that the working party sees many scientific disciplines as having established a broad enough base to support technology "for a considerable time", and so there is now a greater need to train for careers for outside research. This point will cause alarm to some who will see it as the thin end of the wedge by which research, particularly in the physical sciences, is to be gently downgraded. Another reason for changing the emphasis of postgraduate training is to help persuade industry to take high qualifications more seriously. The working party has some hard words for the 'watching old Tom' school in which the sooner bright young students are out of university and learning the job by personal experience the better. A third reason, implicit in much that the working party proposes, is that there is a totally unsatisfactory and wasteful relationship between universities and professional bodies. It is farcical that in 1975 the working party has to suggest that the SRC enquire of these bodies whether certain university and polytechnic courses might be approved for professional training schemes. Fourth, even those who are ultimately to stay in research need education far beyond a first degree if they are not to become narrowly specialised. The provision of such education is at present patchy; many PhD students are able to avoid, or are unable to obtain, any formal training from the day they graduate.

The main recommendations are blunt.

- New, broader degrees to be available, both at master's and doctoral level, in which taught courses have an enhanced significance.
- A higher proportion of compulsory course work to be included in the first year of PhD courses.
- The option of proceeding to a PhD to be open only to those who have taken course work and in addition show aptitude for research.
- Consortia of universities, polytechnics and non-academic bodies to be formed to develop wider ranging courses.

If this looks much closer to the American pattern of postgraduate education, this is by design. The Edwards report is a curious echo of the Flowers report on university computer needs exactly 10 years ago. Then it was IBM which was the object of much admiration; now it is MIT. "We are anxious", says the report, "that the opportunities for graduate instruction offered by MIT should be matched by consortia of British universities, if not by individual universities."

And then finally, lest any academic applegarts be left un-upset, the working party recommend that postgraduates be paid differentially on the basis of the extent to which their work is of economic importance or in the national interest. Since the giving of grants is basically an SRC concern, such a measure could be rapidly implemented, although it is obvious that it could not be applied fairly except in some rather limited but clearly defined instances particularly favoured by SRC, such as joint SRC/SSRC studentships, total technology studentships and the Co-operative Awards in Science and Engineering (CASE) scheme.

The overall impression left by the report is certainly exciting and progressive, and it will speak directly to all those who know and approve of American higher education. But it all reads a little like a lecture, albeit a very good one, prepared by half-a-dozen lively minds gathered round a dinner table. Can the ideas be carried further than oratory? Is there any evidence, for instance, that the disappointing response to the CASE scheme would not be repeated on a much larger scale? Is there any indication that industry is prepared to accept more highly trained entrants? Do people say bad things about MIT's postgraduate education? Is a broad postgraduate training any use without broader undergraduate training than we have now?

That the working party is serious about its proposals, however, is in no doubt. "At a time when we are having to urge belt-tightening on everyone", says Sir Sam, "we wouldn't be proposing something as expensive as this were we not in deadly earnest". □

Nuclear fuel monitoring array at the Fast Flux Test Facility, Hanford, Washington

Rough passage in USA for first breeder reactor

The United States government is planning to spend more than \$10,000 million to develop a liquid metal fast breeder reactor. The programme is the highest priority energy research and development effort supported by public funds, but it has recently come under heavy criticism and it is beset by technical problems. In the second of a series of three articles, Colin Norman reports.

TO its supporters, who include President Ford and his predecessor, the liquid metal fast breeder reactor (LMFBR) could mean the difference between long term prosperity and economic disaster for the United States. But to its critics, who are legion, the reactor is an unacceptable health hazard and an unconscionable waste of taxpayers' money. The debate between those two camps, which has been reverberating for several years, has been getting more shrill lately, but about the only sure fact to emerge so far is that the federal government's costly effort to develop a commercially viable LMFBR is in trouble.

Two separate attempts to shut off funds for key elements in the LMFBR

programme were made in Congress this year. Although they were defeated, similar moves can be expected next year, when the programme's budget will be an even plumper target. Meanwhile, three Congressional committees have been studying the rationale for the programme, individual Congressmen have been taking well publicised pot shots at it, the General Accounting Office has recently issued a gloomy assessment of the effort's cost and timing, and a committee of the National Academy of Sciences is examining the project as part of a mammoth investigation of the entire nuclear power programme in the United States.

It is not difficult to pinpoint the reasons why the LMFBR programme has attracted so much controversy. For a start, it is the single most expensive energy research and development project supported by the federal government; it has also experienced huge cost overruns, has fallen badly behind schedule, and has encountered some nagging technical and safety problems.

But an equally important reason why the LMFBR has come under such concentrated hostile fire is that it is the centrepiece of the Administration's long term nuclear power programme. Without a commercial breeder reactor, the argument goes, light water reactors will run out of low-cost uranium within a few decades, but the LMFBR could prolong the use of nuclear fission as an energy source for several centuries. In other words, if the LMFBR is halted, the nuclear power programme itself will eventually be curtailed, which is reason enough for the breeder reactor programme to have become something of a rallying point for various environmentalist and anti-nuclear groups. Underlying the debate about the need for the LMFBR is a fundamental divergence of opinion on energy policy.

Critics of the programme argue, in short, that if the federal government takes some forceful steps to curb energy demand in the United States, the nuclear power programme could be slowed down. The result, they argue, would be that uranium resources would not be used up so quickly, the breeder reactor would not be needed so urgently, and thousands of millions of dollars which are now being spent on the LMFBR could be channelled into the development of more acceptable sources of power such as solar energy, geothermal energy and thermonuclear fusion.

Needless to say, such arguments are rejected by energy policy-makers in the federal government. They maintain that energy demand could not be cut back sharply without precipitating severe economic problems and that, in

any case, there is no guarantee that alternative sources of energy could be developed in time to preclude the need for the breeder. To cut off LMFBR development now, they argue, could put the United States in such dire straits early in the twenty-first century that the recent Arab oil embargo would seem, by comparison, like a mild inconvenience.

The situation was summed up last June by Dr Robert Seamans Jr, Administrator of the Energy Research and Development Administration (ERDA), the agency responsible for the LMFBR programme. Seamans said that "there is no presently available or prudent alternative" to pressing ahead with research and development on the LMFBR, in the hope that technical and safety problems can be solved in time for the breeder to provide "an essentially inexhaustible source of energy to satisfy a significant share of the nation's energy needs in the next century".

The LMFBR's promise of providing a cornucopia of energy rests on the fact that, by converting uranium wastes into plutonium during its normal operating cycle, it can 'breed' more nuclear fuel than it consumes.

Present-day reactors are driven by a nuclear chain reaction which involves the splitting apart of atoms of the uranium isotope ^{235}U . But unfortunately, only about 0.7% of naturally occurring uranium is in the form of that isotope, the remainder being the isotope ^{238}U which is incapable of sustaining a chain reaction by itself. Before it can be used as a nuclear fuel, natural uranium must therefore be put through an expensive enrichment process, which essentially consists of separating out some of the ^{238}U until the ^{235}U content reaches about 3-5% of the total. At present, ^{238}U removed during enrichment is simply stored as waste, but if it is put into the core of a breeder reactor it can be converted to ^{239}Pu by absorbing fast neutrons. Since ^{239}Pu is capable of sustaining a chain reaction, it can be used as a nuclear fuel.

By the time breeder reactors begin to operate in large numbers, it is argued, enough ^{238}U will have been stockpiled at uranium enrichment plants to provide fuel for the nuclear programme for several centuries. In other words, commercial introduction of LMFBRs would do away with environmentally destructive uranium mining, and would also eliminate the costly process of uranium enrichment. Moreover, because the ^{238}U will already be available, it will not fluctuate in price.

Because of such expectations, breeder reactors came under intensive investigation as long ago as the

1940s. In the mid-1960s, the Atomic Energy Commission chose the liquid metal fast breeder (so-called because it uses liquid sodium to transfer heat from the reactor core to steam generators) as the most promising design, and a similar choice was made in Britain, France, West Germany, Japan and the Soviet Union. Then, in 1971, former President Nixon made the LMFBR programme the highest priority energy research and development programme in the United States, a position it has enjoyed ever since.

The scope and timing of the programme have been revised several times in the past few years, but the latest plan being discussed in the ERDA is geared to achieving commercial introduction of the LMFBR in the early 1990s. The chief milestones on the path to that goal will be construction in 1978 of a test reactor called the Fast Flux Test Facility (FFTF), followed by a 350-MW prototype reactor which is now expected to be completed in 1983, and construction of a large commercial-scale plant capable of generating 1,000–2,000 MW of electricity in 1987. In addition, the ERDA is supporting extensive basic research and testing efforts, and two small experimental fast breeder reactors have already been operated, with mixed success.

Virtually every part of the programme has run into problems. Schedules have slipped badly, and the cost of the effort has skyrocketed. One of the most widely publicised facts about the programme, for example, is that estimates for the total cost of research and development on the LMFBR have increased from \$3,300 million in 1969 to about \$10,700 million now. Although ERDA officials insist that the vast gulf between those estimates can be explained in terms of inflation and by the fact that earlier estimates were not rigorously derived, the spiralling costs of the programme are generating embarrassing publicity.

As for individual parts of the effort, experience so far does not generate much confidence that the latest schedules and cost estimates will be met. The FFTF, for example, was originally expected to be completed by 1973 at a total cost of about \$87.5 million, but the latest completion date is 1978 and the cost is expected to reach at least \$600 million. Designed to test breeder reactor components in a high neutron flux, the FFTF will be a fully operational LMFBR, technically capable of generating 150 MW of electricity. It is now under construction in Washington State but will not actually be used for electricity production.

Similarly, the 350-MW demonstration LMFBR, which will be the next stage in the move towards com-

mercially operating breeders, has also suffered huge cost over-runs and delays. The original completion date of 1978 has slipped to 1983, and the estimated costs have increased from \$699 million to \$1,700 million. Construction of the reactor, in fact, has not even begun; site work is now expected to begin late next year at a location on the Clinch River near Oak Ridge, Tennessee. Recent attacks on the LMFBR programme have mostly been concentrated on the budget for this demonstration reactor, and more are likely next year.

The Clinch River demonstration plant was originally expected to be followed by a series of demonstration plants leading up to a commercial breeder reactor in about 1987, but earlier this year ERDA officials revamped and streamlined the programme considerably. The idea now is to build a large testing facility for LMFBR components in the early 1980s, and to follow the Clinch River plant with a single, commercial-sized reactor in 1987. Design of that reactor will begin next year.

As recently as last March, ERDA officials told Congress that if the LMFBR programme can stay on its present schedule, more than 100 breeder reactors could be operating commercially in the United States by the year 2000. But even that estimate has since been revised. In a long range plan for energy research and development which was published by the ERDA on June 30, it was suggested that only 30–40 breeders could be anticipated by the end of the century. The breeder's impact, that report indicated, will not be felt until early in the twenty-first century.

With all those cost and scheduling problems to shoot at, the LMFBR's critics have never found themselves short of ammunition, and their assaults are expected to intensify in the next few years. The chief source of criticism at the national level is the Natural Resources Defense Council (NRDC), a public interest group whose chief activists against the breeder are Dr Tom Cochran, a nuclear physicist, Dr Arthur Tamplin, a former health physicist with the Atomic Energy Commission, and Gus Speth, a lawyer. In the past few years, the NRDC has generated reams of critical analysis of the federal government's justification for the programme, and it has received some backing on a few of its charges from the Environmental Protection Agency (EPA).

Aside from the cost of the LMFBR programme, the chief disputes will revolve around the following themes. **Uranium resources.** The ERDA has calculated that there is only enough low-cost uranium available in the

United States to provide about 30 years' worth of fuel for each of the light water reactors which will be built before the mid-1990s. In other words, domestic uranium reserves will be totally committed to those nuclear reactors which are brought on line in the next 20 years, and reactors built after about 1995 will begin running out of fuel before their useful life is finished. The ERDA therefore argues that the LMFBR's nuclear breeding capabilities will be needed to prevent the nuclear power industry from grinding to a halt.

The NRDC has challenged those assumptions on two grounds, however. It has argued that the ERDA has adopted unrealistically high estimates for the growth of energy demand, and that it has adopted unrealistically low estimates for the size of uranium reserves, both of which make commercial introduction of the breeder seem more urgent than it really is. Cochran argued before a Congressional committee last June that the commercial component of the breeder programme could be delayed for a decade without any penalty, and that the Clinch River demonstration plant should therefore be cancelled. He suggested that the delay would allow time for more accurate assessments of energy demand and uranium supply, and that the money saved could be better spent on developing solar, geothermal and thermonuclear fusion energy.

Those views have received partial support from the EPA, which suggested in a report last June that commercial introduction of the breeder could be delayed for up to 12 years without incurring economic costs. The ERDA argued, however, that work on the Clinch River demonstration plant should proceed as rapidly as possible in order to help solve some of the more pressing technical problems.

Officials from other government agencies have argued that since there is such utter confusion about long term energy forecasts, it would be foolish to slow down development of the breeder at this stage. The present policy is, therefore, to forge ahead with research and development on the LMFBR and to leave until a later date a decision about whether, or when, the reactor should be introduced commercially.

Plutonium. A large commercial LMFBR programme would inevitably entail the processing, transportation and use of huge quantities of plutonium. And that is a prospect which is worrying many people.

Tamplin and Cochran suggested in a petition to the former Atomic Energy Commission last year that if tiny inhaled particles of plutonium lodge in

the lung, they will give a massive dose of radiation to a tiny area of surrounding lung tissue. They argued that since present standards governing exposure to plutonium are based on the assumption that radiation from inhaled plutonium can be averaged over the entire lung, the permitted dose should be reduced by a factor of at least 100,000.

Although Tamplin and Cochran's argument has been hotly contested by scientists from the former Atomic Energy Commission and, independently, by Britain's Medical Research Council, their theory has continued to give rise to considerable discussion.

Public concern over plutonium toxicity has recently given way to even deeper concern about the possibility that plutonium could be stolen and fashioned into a crude atomic weapon. It is generally accepted that present procedures to guard the theft of potential bomb ingredients would be unsuited to a large scale plutonium industry. For that reason, the Nuclear Regulatory Commission (NRC), which is responsible for regulating the nuclear industry in the United States, recently decided that it could not yet allow plutonium to be recycled as a fuel for light water reactors. That decision will probably have to wait until 1978, the NRC says, when a number of studies of safeguard measures will have been completed.

Fears about plutonium toxicity and safeguards will obviously have to be resolved before a commercial LMFBR programme is allowed to make its debut.

Reactor safety. Although ERDA officials insist that LMFBRs would probably be even safer than light water reactors (chiefly because the liquid sodium coolant has excellent heat transfer properties and because there is a large temperature difference between the melting and boiling points of sodium), nagging doubts about the safety of breeders nevertheless remain.

And those doubts have not been assuaged by operating experience with one of the two experimental fast breeder reactors which have been constructed in the United States. The Enrico Fermi Atomic Power Plant, a 34-MW experimental reactor built in the late 1950s at Lagoona Beach, Michigan, suffered a partial core meltdown in 1966 because of a blockage in the coolant system. The accident, which resulted in radioactivity leaking from the primary containment building, was long considered the most serious mishap in the history of the nuclear power programme. Although ERDA officials rightly insist that such an accident would be extremely unlikely to occur again, the incident has nevertheless been something of a public embarrass-

Tamplin, Speth and Cochran: reams of criticism

ment to the fast breeder programme.

Officials of ERDA maintain that, in the extremely unlikely event that the nuclear core of an LMFBR should melt, the primary containment vessel which surrounds the core would prevent radioactive material from leaking into the environment; a small-scale test on a model of the FFTF has supported such an expectation. Nevertheless, a statement published by the former Atomic Energy Commission early this year acknowledged that "it must be emphasised that technical uncertainties remain to be resolved and work remains to be done before this expectation for systems other than those for which tests have been performed can be thoroughly assessed". And ERDA Administrator Seamans notes that safety questions "must be resolved satisfactorily before any decision may be made to place LMFBRs into commercial use".

Although debate over such issues has been going on in the United States for such time, Congress has only recently begun to examine the LMFBR programme in any detail. Until this year, for example, Congress has been happy to approve hundreds of millions of dollars for the programme without subjecting the matter to any discussion outside the tender confines of the Joint Committee on Atomic Energy.

But the massive cost escalation in the programme has changed all that. Earlier this year, amendments were offered to ERDA's budget authorisation bill which would have halted most of the spending on the Clinch River

demonstration plant for at least 18 months, to allow time for an independent study of the need for the LMFBR. The move failed in the House by 227 votes to 136 and in the Senate by 66 votes to 30, but critics of the programme are not disheartened. Pointing out that they have already received support from a third of the Congress after only a year's effort, they have promised to try again next year.

There is, however, only a small possibility that the LMFBR programme will be halted outright by Congressional action. For one thing, Congress would be reluctant to close down a programme which has such a large potential for meeting energy needs. And for another, the fact that several other countries are vigorously developing LMFBRs will provide a strong incentive for Congress to continue with efforts in the United States. There is also the fact that hundreds of millions of dollars have already been devoted to LMFBR development, an investment which would be difficult simply to write off.

But there is one other factor which is worth bearing in mind. If the thermonuclear fusion programme continues to make sound progress, as it has in the past few years, it will soon require massive outlays on new machines and it would then be competing directly with the LMFBR programme for funds from the ERDA's budget. The LMFBR programme has so far received priority because it is closer to commercialisation, but a significant breakthrough in the fusion programme could, conceivably, change all that. □

international news

Brazil plans 63 nuclear reactors this century

from Bruce Handler, Rio de Janeiro

BRAZIL, which gained world attention earlier this year by signing a unique nuclear technology pact with West Germany, has outlined an ambitious nuclear energy programme that will take it up to the year 2000. The president of a government-run electricity company called Furnas Centrais Elétricas SA, Luiz Claudio de Almeida Magalhaes, announced that by the end of the century, Brazil will have 63 nuclear reactors, with a total generating capacity of 81 million kW.

Magalhaes unveiled this plan in a lecture last month at the Superior War College, a strategy and policy 'think tank' for key civilians and military men which is regarded as highly important by the military-controlled government that runs Latin America's biggest nation. This speech came barely two months after the signing in Bonn of the Brazilian-German agreement, which provides for the transfer to Brazil of the know-how for enriching uranium and building nuclear power plants, along with the actual construction of eight nuclear reactors in Brazil.

Magalhaes explained that although Brazil has immense hydroelectric potential, it won't be enough to take care of the nation's voracious appetite for electricity after 1990. The country already possesses some of the biggest hydroelectric dams in the world, and it has just started building the biggest of them all, a 12-GW giant called Itaipu, across the Parana River, which should go on stream in the mid-1980s. Nonetheless, Brazil must think even further ahead.

A major problem for the development of Brazil is that its booming major cities are located either in the south-eastern part of the country or along the Atlantic coast, whereas its principal untapped rivers, in terms of hydroelectric power, are in the Amazon jungle, 2,000 miles away. And Brazilian urban areas are growing at a mind-boggling rate.

Sao Paulo, the country's industrial capital, has a city-proper population of 7 million and should overtake New York as the Western Hemisphere's largest city within a few years. The Sao Paulo metropolitan area at present has over 9 million people, and even conservative forecasts say this will increase to around 20 million by the end of the century. Rio de Janeiro has a population of nearly 5 million people, not counting the suburbs. Other

Brazilian cities such as Belo Horizonte, Recife, Porto Alegre, Salvador and Fortaleza—which most outsiders have never heard of—have already reached the 1 million mark.

Since Brazil produces only around one-fifth of the crude oil it needs every year, there is only one solution for its future energy requirements; nuclear power. Brazil's first nuclear generating station, a 627 MW installation at Angra dos Reis, 130 miles from Rio, is to begin operating in early 1978. This plant was built by Westinghouse Electric of the United States, but because of restrictions imposed by the US government, Brazil did not acquire any nuclear technology in connection with the project and it had to send uranium to the United States to be enriched. Because of Brazil's undeniable need for nuclear energy in the future, Brazilian government officials saw the nuclear security limitations dictated by Washington as extremely prejudicial and encumbering and so turned to Germany for nuclear expertise.

Two German-designed reactors of 1.3 GW each are to be built at Angra dos Reis, practically next door to the American plant, and they should come into operation in the mid-1980s. Six more German reactors, all in the 1.3-GW range, are to go on stream by 1990, serving Sao Paulo, Rio, Salvador and Recife.

Magalhaes did not say who would design and build the 54 additional reactors planned for the year 2000. Theoretically, by 1990 Brazil will have learned all the tricks of the trade from the Germans and could design the remaining reactors itself, contracting out specialised work when necessary. The Brazilian energy official said the 54 reactors will all be near big cities.

Magalhaes told his audience at the Superior War College that Brazil would be "extremely vulnerable" if it depended too heavily on hydroelectric power, although he did not elaborate on this. His main objective was to convince possible sceptics that Brazil did the right thing by making the big nuclear power push now. Magalhaes noted that Brazil's "useable" hydroelectric potential will run out by the end of the century. On paper, Brazilian rivers could provide 120 GW of power (the capacity installed at present is around 15 GW). But Brazilian officials, who have studied hydroelectrical projects in the Soviet Union, which has similar problems of distance, are less than enthusiastic about the high cost and inefficiency of long power lines.

Magalhaes was also bluntly unenthusiastic about Brazil's chances of significantly increasing oil production. The state oil company, Petrobras, which has a monopoly on drilling and refining, has been spending about \$275 million a year on prospecting, but production has remained about the same for the past several years. There are encouraging off-shore oil finds but, in spite of fantastic predictions of self sufficiency by certain government officials, it still seems too early to tell how good these new discoveries are. Meanwhile Brazil continues to spend more than US\$3,000 million a year on expensive crude oil from the Middle East. There have been suggestions that Petrobras should let big foreign oil companies look for oil in Brazil under service contracts but these have been rejected, mostly for nationalistic reasons.

At almost the same time that Magalhaes was explaining why Brazil has no choice other than nuclear energy as its prime source of energy in the future, the Mines and Energy Minister, Shigeaki Ueki, announced two new uranium discoveries. A big question mark in the Brazilian-German deal is whether Brazil actually has enough uranium to be able to carry out its ambitious plans for nuclear power. The minister said that two uranium deposits had been located in the central state of Goias and that rough preliminary estimates indicated a total of 1,500 tons of uranium ore. If this estimate holds up under further investigation, it will mean a 14% increase in Brazil's known uranium reserves. □

THE Science Research Council (SRC), hit for the second consecutive year by a reduction in its spending power, is to review its allocation of funds in an effort to maintain a balanced research programme in Britain. Several measures have been suggested, among them the provision of a larger proportion of available funds to university research, but the most interesting innovation in the long term is the introduction of industrially based research programmes designed to attract investments from commercial interests.

Speaking last week following the publication of the council's Tenth Annual Report, the Chairman of the SRC, Sir Sam Edwards, ranged freely over the council's record during the past year and its strategy for the year ahead, and made particular play of the newly approved polymer research programme established to encourage cooperation between academic and industrial interests. Spread over a period of five years, the project will operate on a budget of £2.5 million, which will include contributions from the British Plastics Federation and the British Rubber Manufacturers' Association, and will be responsible to a directorate that will "initiate and oversee a closely coordinated research programme" involving both the universities and industry.

To judge from Sir Sam's enthusiasm, the council sees the adoption of the new programme as a significant development in the running of research and plainly hopes that industrial interests will eventually be encouraged to provide support for similar programmes from which they can ultimately expect to benefit.

Certainly, the council's breakthrough in that area of research funding has come at an apposite moment. Because of inflation, the council's budget for 1974-75, just over £85.5 million, was 2% lower in real terms than in the previous year; a similar reduction is forecast for 1975-76. The effects of inflation are, moreover, aggravated by the council's commitment to the European organisations CERN and the European Space Agency (ESA), which is guaranteed in Swiss currency and which has taken up an increasing share of the budget as the pound sterling has weakened. To make the best of the remainder of the budget, which is divided between bread-and-butter support for research and facilities in the universities, and the financing of major projects which require a high expenditure in a single area of research, the council is to implement cuts in the latter sector.

Already the council has completely abandoned two of the fifteen major

projects listed in last year's report—the European X-ray satellite and the Mark VA telescope—in spite of their admitted scientific importance. And of the seven listed in the present report (which include the Northern Hemisphere Observatory and the Electron-positron Intersecting Complex—EPIC) Sir Sam declared that he could see at least two of them "going overboard" during the coming year. Questioned on which they might be, he chose not to show his hand, adding only that it

Round Britain

would cost about £74 million to adopt all seven whereas the sum available would be nearer last year's figure of £25 million. It seems reasonable to speculate, however, that with the rising cost of space research the NASA satellite project will never see the light of day.

The council's affirmation of support for university research is highlighted by the timely approval of the laser laboratory which is to be established at the Rutherford Laboratory in Chilton, Oxfordshire, at a cost of £5.7 million. It will provide a central research facility for the universities and polytechnics. The original involvement of the UK Atomic Energy Authority in the project, which was from the outset somewhat uncertain, has now been withdrawn altogether.

As far as research training is concerned, the number of postgraduates studentships will be reduced by 300 to about 3,600 in the coming year. This cut comes in spite of a 25% increase in the number of applications and means that only 14% of science and engineering graduates will be catered for. Nonetheless, the council has not been entirely negative on that front, having proposed a facelift for research training (see page 433).

More generally, the report announces the council's intention to "sharpen" the criteria used in the selection of particular fields for research funding, and though Sir Sam was characteristically phlegmatic on what precisely that means, the report itself indicates that it is the programmes considered of national importance that will receive the most favourable consideration.

● The decision to press on with the German ring accelerator PETRA in Hamburg sounds like the death-knell for its British competitor EPIC. Although the commitment of 14 million Deutschmarks is only for buildings to house the machine, approval for the machine itself cannot be far behind. Dr Godfrey Stafford, director of the

Rutherford Laboratory, at which EPIC would have been housed, was not only disappointed at the German decision, but feels it has some unfortunate implications for the future of high-energy research. The European dimension to such research, represented by CERN, and which he believes EPIC, with international funding support, would have maintained, is in danger of reverting to national rivalry. Recent unilateral initiatives by the French (with GANIL) and now the Germans cannot but put more global programmes under serious pressure.

● The United Kingdom Atomic Energy Authority (UKAEA) also presented its annual report last week, and the general tone of the peroration of its Chairman, Sir John Hill, was one of relief at the end of several years of bickering over the way British nuclear policy should proceed. During the past year the government decided to go for a steam generating heavy water reactor, while maintaining the national effort on the fast reactor; during the coming year the first two advanced gas-cooled reactor (AGR) stations at Hinkley Point and Hunterston should come on line, and the prototype fast reactor, which has been delayed by various teething troubles, should come into full operation. After 10 years of vast overspending, delays running into years, and an industrial structure which was, to say the least, unhelpful to the production of any kind of energy, the authority's chairman was wiping his brow and brightening at the prospect of a New Era in nuclear engineering. But if the progress of the £45 million Prototype Fast Reactor at Dounreay is anything to go by, the UKAEA's optimism could turn out to be the very stuff of pipe dreams.

● A piece of information from Sir John Hill which was immediately seized upon by the media was the news that Harwell had re-started a programme to examine the possibility of disposing of dangerous radioactive waste in geological strata and the ocean depths. Sir John regretted that he could not say where the Harwell men were looking or when the UKAEA might think of dumping; it was all very much a general enquiry at the moment. Quite coincidentally, the Natural Environment Research Council (NERC) announced last week that Britain was to pay \$1 million a year to join in the International Phase of Ocean Drilling (IPOD) of the Deep Sea Drilling Project (DSDP).

The term "International Phase of Ocean Drilling" is in fact a euphemism for a phase which might more accurately have been called the survival-by-a-hair's-breadth period. The DSDP, which has been supported almost unilaterally by the USA since its inception

In a controversial report published this week, a committee of the National Academy of Sciences (NAS) has convincingly demonstrated how little we know about the potential long term consequences of a full-scale nuclear war. The committee attempted to assess the magnitude of physical and biological damage in regions far removed from the target area, decades after a massive nuclear attack. Not surprisingly, it has suggested that there are huge areas of uncertainty—such as the possibility that a significant climatic change could be triggered—but it could predict no single effect serious enough to wipe out human life completely.

The report has raised considerable controversy because, aside from the emotional nature of the subject matter, it is open to a wide range of interpretations. Thus, Dr Philip Handler, President of the NAS, stated in a letter printed as an introduction to the report that the committee has concluded that *Homo sapiens* would survive the "horrendous calamity" of a massive nuclear exchange, while the Federation of American Scientists (FAS) suggested in a commentary on the report that the uncertainties in the calculations render such conclusions unwarranted.

The study, which was carried out for the Arms Control and Disarmament Agency (ACDA), took as its starting point a war resulting in the detonation of about 10,000 megatons of nuclear explosives in the Northern Hemisphere—equivalent to about half the destructive capacity of the world's nuclear arsenals. The committee concentrated its attention on phenomena likely to occur "at distances on the order of continental separations from the detonations", and it made no attempt to analyse possible economic and political consequences from such a holocaust. Findings include:

- Perhaps the most significant worldwide effect may result, not from radioactive fallout, but from massive destruction of the ozone layer. The committee notes that a major nuclear

exchange would inject huge amounts of nitric oxide into the stratosphere, which in turn could destroy between 30 and 70% of the ozone layer in the Northern Hemisphere, and about 20–40% of the layer in the Southern Hemisphere. Although much of that destruction would be repaired by natural processes in three or four

After the Third World War

by Colin Norman, Washington

years, it may take as long as 40 years for the ozone layer to be restored completely, the committee reckons.

The consequences of such an event would be a very large increase in the amount of ultraviolet radiation reaching the Earth's surface; this would damage plant life and present a severe health hazard to animals, including man. The committee notes, for example, that increased exposure to ultraviolet radiation "might have a significant impact on a great variety of [plant] species . . . and possibly could have serious implications for the ecosystem of which (particularly sensitive species) are a part". As for food crops, the committee suggests that plants such as peas and onions could be killed by large increases in ultraviolet radiation. The effect on man would be to increase the incidence of skin cancer in mid-latitudes by up to 30%, and "incapacitating cases of sunburn in the temperate zones and snow blindness in northern countries" would be expected.

- Radioactive fallout in the Northern Hemisphere would average about 1 Ci km⁻², but there would probably be "hot spots" where the fallout could be an order or magnitude greater. The committee states that "there would be no widespread effect" on plants from fallout, but in the hot spots, "minimum damage to ecosystems dominated

by radio-sensitive plants might occur". Some foods may become contaminated at levels "approaching the upper limits of present standards", however.

The effect on animals would, on the other hand, be more pronounced. An increase of 2% in the incidence of cancer would be likely, and a similar increase in the incidence of genetic disease would also result.

- As for effects on climate, the committee notes that a large nuclear exchange would inject vast amounts of dust into the atmosphere, which would reduce the amount of solar radiation reaching the Earth and possibly reduce global temperatures as a result. Moreover, destruction of a large part of the ozone layer might also lead to a reduction in temperatures. Even small changes would have serious implications for crop production, and the committee notes that "substantial changes in weather extremes . . . which could be of major importance to agriculture, have also been related plausibly to small changes in global mean climate". The committee said, moreover, that it could not rule out the possibility that a small perturbation in global temperatures "also might lead to major global climatic changes".

What are the implications of such findings for policymaking? Opinions vary. According to Dr Fred Iklé, Director of the ACDA, the committee's findings underline the futility of all-out nuclear war, because they suggest that there may be a serious ecological backlash from a massive nuclear attack.

But the FAS suggested in its statement that the conclusion that mankind might survive a nuclear holocaust has little relevance to public policy.

The committee should have recommended getting rid of all US and Soviet nuclear bombers, which would eliminate about 80% of the world's nuclear megatonnage, thereby reducing potential long-term effects of nuclear war, says FAS. □

in 1968, was expected to cost \$14 million in the present fiscal year, and the chances are that it would have collapsed in a bankrupt heap if five foreign governments hadn't agreed to bail out the project. Very broad hints were dropped during hearings of the House Appropriations Sub-committee last February that Congress might only look favourably on requests for more funds if an international interest could be demonstrated—and demonstrated in dollars and cents. The Soviet Union and Japan have also signed up for \$1 million worth of interest, West Germany is renegotiating an involvement

of two years' standing, and France is also expected to buy in at the going rate, leaving the USA to find the remaining \$9 million.

Since the information gathered by the DSDP in its pre-international phase was fairly readily available to friendly nations at something less than \$1 million a year, it seems reasonable to ask why the UK should bother laying out money. The answer is that if the UK (and the other four volunteers) hadn't, then there wouldn't have been any further information to receive at bargain rates or any other: that the UK would now have immediate access

to results, but that the emphasis in British participation was chiefly on the economic and technological benefits to be gained. This is meant to mean that the UK will be in a better position to exploit seabed resources (if and when the good ship *Glomar Challenger* happens on any) and hard scientific know-how, and that the exercise will develop the nation's deep-sea technology experience, presumably to the benefit of North Sea oil operations. Perhaps it will also provide answers to interesting questions like: "Where is there a nice spot to dump a ton of radioactive waste?" □

TO irradiate or not? That is the question. The issue involved is simple: is irradiated food—in this case, wheat—safe for human consumption? A year-old row over the matter between two premier research institutions, one of which belongs to the Department of Atomic Energy (DAE) and the other to the Ministry of Health, has recently burst into the open. And as wheat is the staple diet of much of the Indian population, the question has assumed enormous significance.

Work on the radiation preservation of foods has been going on at the DAE's Bhabha Atomic Research Centre (BARC) in Bombay for quite some time. The BARC has long been a proponent of the radiation method and has been urging the authorities to grant health clearance to specific low-dose food irradiation processes.

"Chemical disinfection methods such as fumigation require repeated application because they do not eliminate insect eggs. They may also leave harmful residues in the treated grain. Irradiation, on the other hand, is a one-shot process that completely kills or sterilises the common grain pests, their pupae, larvae and even the eggs deposited inside the grains." Commending the radiation method thus, Director of the BARC, R. Ramanna, said in a lecture at a Bangalore college last year: "The work carried out at the BARC, especially on wheat, potatoes and onions, clearly shows that preservation of foods by radiation is not only economic but safe according to all standards; the earlier we adopt this method the better it is".

But the National Institute of Nutrition (NIN) in Hyderabad has stated (in its annual report for 1974) that irradiated wheat could be hazardous to health. Specifically, it claims to have found that: (a) consumption of irradiated wheat by both animals and humans caused them to develop polyploidy—a condition characterised by more than the normal number of chromosomes in cells; (b) rats which were fed on irradiated wheat and which developed abnormal or polyploid cells transmitted these chromosomal abnormalities to their offspring; (c) mutations took place faster in animals that ate irradiated wheat; (d) there was a significant reduction in reproductive cells in malnourished rats on irradiated wheat diet; and (e) incidence of polyploidy was reduced if irradiated wheat was stored for 12 to 14 weeks before consumption.

As soon as these findings were made public the DAE responded by repudiating the NIN claim. It maintained that its own experiments (at the BARC) had not revealed any of the 'hazards' referred to by the NIN. In support, the DAE statement mentioned that, on the

basis of similar feeding trials with laboratory animals, several countries (including the USA, the USSR, Canada, France, Holland and Denmark) had declared a variety of irradiated foods as safe and wholesome for unlimited human consumption. Moreover, specialised UN agencies like the Food and Agriculture Organisation (FAO) and the World Health Organisation (WHO), it said, had rejected contentions that irradiated wheat was meant exclusively for animals and not for human beings. The DAE also refuted the charge that it had "already spent crores" in setting up laboratories

Row over irradiation of wheat

from Narender K. Sehgal, Jullundur

and equipment for radiation preservation of food.

Following this the NIN repeated its earlier warning about hazards from irradiated wheat and answered criticism of its findings. It said it had experimented with children only after "totally accepting" the DAE claim that its studies had shown irradiated wheat to be "harmless". (Although irradiated wheat was earlier found by the NIN to cause polyploidy it went ahead and fed this diet to five malnourished young children aged two to five for six weeks. This attracted severe criticism from many quarters.) But, "when we fed children irradiated wheat and found abnormal cells in circulation the study was promptly terminated", the statement added.

The DAE observation that polyploid cells in fact occurred naturally in humans and animals was countered by pointing out that in its (NIN's) experiments "feeding of irradiated wheat was consistently associated with a four- to ten-fold increase in the number of polyploid cells"; this was found to be true in rats, mice and monkeys irrespective of the protein content of the diet or the age of the animal. Although conceding that the precise significance of increased polyploidy was perhaps something that could be debated, the NIN statement pointed out that this condition had been generally associated with a kind of cancer.

The NIN denied the DAE charge that it had either underplayed or tried to conceal its own finding that the 'hazards' mentioned by it were absent when irradiated wheat was stored for over 12 weeks before consumption. But, the statement said, the NIN studies had further shown that the production of aflatoxin poison was considerably greater in stored irradiated wheat and potatoes than in the corresponding unirradiated foods. The NIN

also noted that, in the case of onions and potatoes, rotting rather than sprouting was a major problem in India and that irradiation seemed to accelerate rotting even though it did stop sprouting. (This observation was in reference to the fact that the BARC had been devoting considerable attention to preventing sprouting in onions and potatoes, instead of concentrating on the problem of rotting.)

The NIN statement said in the end that it did not look upon the matter as a prestige issue; "we are always prepared to look in all objectivity at any new evidence which may throw an entirely new light on the problem".

While the two institutions continue to exchange charges and arguments over apparently conflicting results, an expert technical committee has called for further "joint studies by the DAE and the NIN on post-irradiation storage problems of irradiated wheat and potatoes". This committee, headed by Dr M. S. Swaminathan (Director-General of the Indian Council of Agricultural Research), was set up last year at the instigation of the Prime Minister to go into the whole matter of the safety of irradiated wheat, onions and potatoes.

The committee, in its report submitted recently to the Ministry of Health, has steered clear of the safety question. In view of the problems of aflatoxin production during storage of wheat and potatoes (in the latter case, rotting as well), the government, the committee said, could consider clearing irradiated wheat and potatoes for sale only after insisting on proper storage—a minimum of six months for wheat and four months for potatoes.

The committee based its report on studies in India on wheat and on data from other countries in the case of potatoes, since none was available from India. In the case of onions, no studies had been carried out in India and the committee were of the view that studies abroad were "not yet conclusive about the safety of irradiated onions for human consumption". So it declined to make a recommendation at this stage.

In view of the serious differences between the NIN and the DAE over irradiated wheat, the Swaminathan committee called for an expert evaluation of the data by a team consisting of a statistical expert from the Maharashtra Association for Cultivation of Science and a geneticist from the Jawaharlal Nehru University. The committee also suggested that an inter-ministerial technical group should examine the techno-economic questions, the cost-benefit analyses and the feasibility of adopting radiation technology for food preservation on a large scale. □

ON August 10, on the beach at Cape Canaveral in Florida, I saw a red-headed man, sunburned to look like a boiled lobster, applying novocaine cream to his glowing back. The only unusual circumstance was that the man was Mike McElroy, whose field is the physics and chemistry of planetary atmospheres and who has loudly warned us against the ultraviolet perils of destroying the ozone layer by using aerosol spray cans. Aha, I thought: one foot in the sea, and one on the shore—to one thing constant never. For surely he, of all people, should have kept his shirt on.

The proposed ban on aerosol spray cans is a model of scientific virtue. It will save the sacred Environment of our fragile space-ship Earth from the excesses of rampant technology. It will prevent cancer. It will enable academic atmospheric physicists to cover themselves with glory—their abstruse field is Being Put To Use, while visions of research grants dance through their heads. Investigation of the subject is “a natural” for the techniques, instrumentation and vehicles of the space programme, and so it will be a first-rate spin-off for NASA. The ban may even save some metal from being used in cans, and it will benevolently force people to use their flabby muscles in wielding paint brushes. The New York Subway System will perhaps be able to clean up its cars, which are now hideously festooned with paint applied from spray cans by the vandals who also deface rocks by the roadside. Spray-on armpit deodorants will be replaced by the roll-on type, and the consumer will pay the same astronomical mark-up for a cent's worth of some aluminium salt to close the axillary sweat glands. Furthermore, no

Spray no more, ladies

THOMAS H. JUKES

one will ever be able to prove the ban was not needed—there is no neighbouring planet that could be used as a control. Private industry doesn't have a chance—the public got along very well before aerosol spray cans were introduced, and the task of the courts in denying appeals against a ban is made childishly simple by the magic word “cancer”.

Indeed the National Resources Defense Council has intoned “For every year that the banning of these aerosols is delayed, evidence shows that an additional 2,000 to 4,000 people will be stricken with skin cancer”. (Note the expletive use of the word “stricken”.) What evidence shows this, I wonder? Ultraviolet light has been reaching the skin ever since human beings first appeared. How many cases of skin cancer are caused by sunlight; what is the incidence at different latitudes; and how is it related to the percentage of the body surface that is exposed? Someone must have done some extrapolating to come up with the figure of 2,000 to 4,000 people, especially when

the effect of aerosols on the ozone layer is a matter of debate rather than measurement. And then, of course, ultraviolet light protects against rickets. . . . If the danger of cancer from solar ultraviolet light is so great, why not suggest that people keep their clothes on? From Sydney to Stockholm, the near-naked and naked white-skinned legions loll on beaches, seeking to acquire the shadowed livery of the burnished sun, and to hell with skin cancer.

A few cynical sceptics remain unconvinced. Professor Richard Scorer says it is Much Ado About Nothing. He has been rude enough to say that the talk of the threat to the ozone layer is a publicity gimmick concocted by doomsayers using scare tactics to gain headlines, and that most of the organic chlorine compounds now measured in the stratosphere are of natural origin, or from the deliberate burning of vegetation. Personally, I rather favour his thesis that the environment is full of checks and balances, and “is not as frail as some people picture it”. But heaven forbid that I should suggest that a large amount of research on this latest scare is not needed; it will train young scientists, and it will help to restore badly needed public confidence in the social values of research in the natural sciences.

And perhaps—who knows?—we may eventually be able to ride on the New York Subway, and read the advertisements for deodorants unmarred by paint from aerosol spray cans! But I am afraid that I underestimate the ingenuity of industrial chemists, who undoubtedly are hard at work to devise new spray propellants that do not destroy ozone, thus converting all our sounds of woe to hey-nony-nony.

THE first protocol of the Anglo-Soviet Joint Commission on Health Cooperation, signed on September 25, 1975 by Mrs Barbara Castle, Secretary of State for the Social Services, and Professor Boris Petrovskii, Soviet Minister of Health, represents the first stage in the implementation of the Anglo-Soviet Agreement on Cooperation in Medicine and Public Health which resulted from Mr Harold Wilson's visit to Moscow last February.

The agreement itself is a wide ranging document, dealing in general terms with “exchanges of information on new equipment, pharmaceutical products and technological developments related to medicine and public health,” reciprocal health-service arrangements for British and Soviet citizens requiring immediate medical treatment while in the other country, and the elaboration of (so far unspecified) programmes of

Healthy exchanges

from Vera Rich, London

joint research. Only one section—Article 2A—names any specific subjects for cooperation, and it is precisely these, influenza and other communicable diseases, ophthalmic diseases, and the organisation of medical care for traumatic and cardiac emergencies, which are the subject of the present Protocol.

Under the terms of the Protocol up to 25 man-months during the first year of its operation may be spent by each side on research in the other's country, with due arrangements made for the supervision of research and the pooling of results. The institutions involved in the exchange will be the

Institute of Ophthalmology of the University of London and the All-Union Institute of Ophthalmic Diseases; the Public Health Laboratory Service, Colindale, and the Moscow Institute for Virus Preparations; and the Medical Research Council Accident and Burns Unit, Birmingham, and the Moscow Institute for Emergency Medical Services.

Although the agreement makes provision for sending patients for treatment from one country to the other the Protocol stresses that in view of the “high level of development” of both health services, such exchanges are envisaged in exceptional circumstances only, and it seems likely that cases such as that of the Russian baby Irina Chudnovskaya, who has already been treated at the Brompton Hospital for a heart condition, will remain relatively rare. □

Radon emissions

SIR,—Wendy Barnaby (August 28) writes on the problem of radon emission from the tailings of uranium milling in Sweden. This problem would arise from the large volume of uranium shale that has to be treated. She describes Professor Robert O. Pohl's report that "radon can escape more easily from the broken ground of a mine than from an undisturbed terrain". This report is well known among Swedish experts. Thorium-230, a metallic chemical element, and radon-222, a noble gas formed from uranium, can be found wherever there is uranium in the Earth's crust—not only in uranium ores and mines but also in primary rock.

In 1965, the Swedish Atomic Energy Company (AB Atomenergi) started operations at Ranstad where there is a large uranium deposit. From the very beginning, the emission of radon from the leaching residues has been studied. It has been shown that the emission from recently deposited residues is approximately equal to that measured in the open pit on the uranium shale bench. It has also been shown that the emission of radon from the restored tailings is of the same order of magnitude as that from the undisturbed terrain within the open pit area. In Ranstad, large scale tests have been made during the past few years on the deposition of leaching residues. The residues were laid out in stockpiles after mixing with fine-ground limestone and packed with a vibrating roller. After that, the area was covered with earth from the open pit and seeded.

As well as giving the landscape an attractive finish and making it possible to use the ground for agricultural purpose, the emission of radon has been minimised.

Cancer at work

SIR,—Your article "Cancer at work" (September 18) is admirable in that it draws attention to environmental carcinogens. It is regrettable, however, that no mention is made of the painstaking work of S. A. Henry of the Medical Inspectorate of Factories in finally convincing authorities of the

risks of tar and in particular of lubricating oils used outside the cotton industries (*Cancer of the Scrotum in Relation to Occupation*, Oxford University Press, 1946). The considerable emphasis laid on the historical background leading to the recognition of these carcinogens does, moreover, distract attention from the fact that these problems are still with us. The sentence "Although less common, scrotal cancer still occurs in industry in conditions in which men are exposed to lubricating oils" is a gross understatement of the present situation. Although there are geographical variations in the occurrence of lubricating-oil cancer which are as yet unexplained, the incidence in the West Midlands not only of scrotal cancer but of skin cancer and possibly of lung cancer is a cause for considerable concern.

University of Birmingham, UK

Leprosy treatment

SIR,—Being engaged in leprosy control work in India, I daily face exactly those problems mentioned by Browne and Davey (May 15) as the main obstacles in implementing regular and sustained treatment of leprosy patients, namely, the social aspects of leprosy and the patients' attitude to leprosy.

I would like to add one more human factor and that is the importance of motivated staff. Much has been written about planning, education of the public and the approach of the leprosy patient, but little or no attention is usually paid to the field worker. Yet he is the key person in the strategy for leprosy. It is not lack of planning or of effective drugs or of a vaccine which has caused so many leprosy control programmes to founder but lack of dedicated and competent field staff. So our first concern must be to give field workers the right motivation.

My second point concerns the treatment of leprosy. Both Browne and Davey, and Crawford (March 20), refer to sulphones only but nowadays no leprosy control unit can function properly unless it has Lampréne at its disposal as well. The absolute indication for Lampréne is resistance against Dapsone. This was very rare, but according to Browne and Davey "it is not now, and the recent figures coming from countries where the problem has

been adequately investigated are very disturbing to say the least."

The greatest advantage of Lampréne, however, is that it has both bacteriostatic and anti-inflammatory properties. Thus treatment of Lampréne can be continued during reactions, whereas treatment with Dapsone is often discontinued during reactions, either by the doctor or by the patient himself. This may ultimately lead to resistance against Dapsone in lepromatous patients who are prone to reactions. It is for this momentous group of patients that Lampréne is absolutely indispensable. In Dichpalli, with approximately 10,000 leprosy patients receiving treatment, 2 to 3% require Lampréne and the proportion is still increasing.

L. M. HÖGERZEIL
Dichpalli, India

Czech conference

SIR,—I recently registered as a participant in the International Conference on Low Radioactivity Measurement and Applications (LRM) in Czechoslovakia (October 6–10,) paid for the conference fee, and got written acceptance of my participation and hotel lodgings. Also a visa for that particular conference I received from the Czechoslovakian Embassy in Bonn.

On September 17, I received a letter from the organiser (also in Czechoslovakia) to say that I would not obtain a visa to attend the LRM conference due to "news from the Czechoslovak ministry of Foreign affairs." The Bonn Czechoslovakian embassy told me on demand that the validity of my visa could by no means depend on such a letter, and that I might still travel there.

Later I received a telegram from the organiser telling me in a harsh tone and without giving reasons that "we cannot accept your participation in the conference."

I never had any political or other differences with my own or foreign countries, but I would not think of participating in this conference after such an incredible sequence of events. May I suggest to Czechoslovakian politicians: If you really want to build up effective scientific research why not treat your scientists better and their guests in a less arbitrary manner?

Cologne, FDR

news and views

It is a long time since the discovery of bacterial transformation demonstrated that small amounts of foreign genetic information can be introduced into a living cell, and can function there. The explosive development of techniques for genetic and general biological experiments on eukaryotic cells in culture has led naturally to the search for an analogous system for the transfer of genetic information between cells of higher organisms.

Quite substantial progress has been made at several different levels, and it is now clear that the genetic information of complex organisms can be introduced into a foreign cell, and can function satisfactorily in this new environment. Whole nuclei can be introduced mechanically into the enucleated cytoplasm of another cell type (Gurdon, *Adv. Morphogenesis*, 4, 1; 1964). Somatic cell hybrids, usually made with inactivated Sendai virus (Harris, *Cell Fusion*, Oxford University Press, 1970; Ephrussi, *Hybridization of Somatic Cells*, Princeton University Press, 1972), initially also produce two or more different functional nuclei within one cytoplasm, but this is followed by nuclear fusion resulting in mononucleate cells containing chromosomes of both parental types. In many situations, particularly where the cells used are from different species, these hybrids subsequently lose chromosomes of one parental type, leading eventually to cell lines which contain relatively few 'foreign' chromosomes within their nuclei. Chromosomes introduced in this way can express their genetic information, and this system has been extensively used for the formal genetic analysis of human chromosomes (*Rotterdam Conference*, The National Foundation, 1974), studies on regulation of gene expression and so on.

An extreme example of chromosomal segregation in hybrid cells is provided by situations in which an enzymatic function of one parental type is retained in the hybrid, but no corresponding chromosome can be detected in the karyotype (Schwartz *et al.*, *Nature new Biol.*, 230, 5; 1971; Klinger and Shin, *Proc. natn. Acad. Sci. U.S.A.*, 71, 1398; 1974). The probable explanation is that a chromosomal rearrangement has occurred, translocating a small segment of the donor genome into the host cell's karyotype. Thus, a microscopically undetectable amount of foreign genetic

Information transfer in mammalian cells

from M. Bobrow and E. Solomon

information is integrated, with some degree of stability, into the host cell genome.

Many workers have attempted to demonstrate the uptake of isolated chromosomes or purified DNA by eukaryotic cells. Only recently, however, have any persuasive examples of this type of phenomenon been described. McBride and Ozer (*Proc. natn. Acad. Sci. U.S.A.*, 70, 1258; 1973) incubated isolated Chinese hamster chromosomes with mouse fibroblasts deficient in the enzyme HPRT. The absence of this enzyme makes cells unable to grow in selective medium containing aminopterin. In such a medium, McBride and Ozer isolated cell lines which had acquired the hamster HPRT enzyme, thus correcting the genetic deficiency of the mouse cells. Similar results have been obtained on incubating mouse cells with isolated human chromosomes (Burch and McBride, *Proc. natn. Acad. Sci. U.S.A.*, 72, 1797; 1975; Willecke and Ruddle, *Proc. natn. Acad. Sci. U.S.A.*, 72, 1792; 1975).

The difficulty in experiments of this sort is to distinguish genuine transfer of genetic information from mutational or induced changes occurring in the host cells themselves. Most enzyme-deficient cell lines used in selective culture systems do have a low but detectable rate of spontaneous reversion to the enzyme-producing phenotype. Results such as those of McBride and Ozer are made credible by the great care taken in characterising the HPRT enzyme in the 'corrected' cells, by a variety of techniques, as being of donor and not of host origin.

In none of these cases was there any identifiable donor chromosome present

in the karyotype of the derived cell lines. Some of these 'corrected' mouse cell lines are quite stable in culture, and are possibly again the result of small chromosomal rearrangements, with fragments of donor chromosome being inserted into the host karyotype. The size of fragment transferred must, in all these experiments, be pretty small (estimated as less than 1.5% of the human genome) as no donor enzymes have been detected in the resultant cell lines other than the one (HPRT) specifically selected for by the culture system. The reason for the integrated fragment being so small is not yet apparent. This unfortunately limits the use of the technique for genetic experiments other than those dealing with a selectable enzyme itself, or genes very closely linked to it. □

A hundred years ago

Oceanic Circulation

MR. CROLL'S statement (vol. xii, p.494), that the North Atlantic in lat. 38° is above the level of the equator, is based partly on the *Challenger* soundings and partly on Muncke's determinations of the thermal expansion of sea-water, which, however, were not made on sea-water at all, but on a saline solution prepared for him by Leopold Gmelin, according to data furnished by the incomplete analyses of Vogel and Bouillon La Grange. As Mr. Croll's statement depends on such very minute differences of volume, I am led to ask him to compare the rate of expansion of real sea-water, as determined by Prof. Hubbard, with Muncke's table; he will notice a discrepancy sufficiently wide to make it a matter of interest to ascertain how far the employment of the American observations may serve to substantiate or modify his conclusion.

G. E. THORPE

Yorkshire College of Science,
Oct. 11.

from *Nature*, 12, 514; October 14, 1875

EVERY schoolboy is told that gravity is only attractive. Unlike selenite—that amazing substance written into science fiction by H. G. Wells—ordinary matter always falls towards other matter

This asymmetric property of gravity used to pose a problem to inventors of model universes. What stops everything in the Universe from falling together at one place? During the adolescence of his theory of general relativity, Einstein applied his newly proposed gravitational field equations to a simple model universe. He was dismayed to find that this universe would not stay still—it had either to collapse or expand. Interpreting this circumstance as a defect of the theory, he set about tampering with the field equations to put the matter right. He was able to add an extra term to the equations, without compromising the basic physical principles of the theory, which did, indeed, enable a static model universe to be constructed. The result was a novel curiosity—a universe which was finite in volume, yet unbounded; a consequence of the curvature of space actually closing the universe up on itself. Included in the extra term is the 'cosmological constant'.

The physical effect of this extra term is to introduce a repulsion in the gravitational action between distant matter. This repulsion is negligible over terrestrial distances, but can dominate on a cosmic scale. By doing a balancing act between "ordinary" gravitational attraction and cosmic repulsion, Einstein's model universe could remain static.

By a quirk of fate, scarcely had the

Is the Universe running away with itself?

from P. C. W. Davies

model been constructed than it was discovered by Hubble that the Universe was not static anyway, but in a state of general expansion. New models of this expanding Universe had already been constructed by Friedmann, and the cosmological constant was not needed, which was a relief to the physicists, who naturally regarded this term as rather contrived. Since then, most cosmologists have been happy to drop the extra term (although it has been resurrected on a number of occasions, principally because it can enable the Universe to be somewhat older than its expansion rate suggests, by delaying in a "nearly static" phase). This philosophy has long fitted in nicely with observation, which has shown the cosmological expansion rate steadily slowing down with time. Such a deceleration is explained naturally by the supposition that the galaxies are pulling back on each other as they move apart. If there was cosmic repulsion, then the galaxies ought to be accelerating not decelerating. A simple calculation shows that this acceleration would actually be exponential—a cosmic runaway motion in which the Universe would for ever expand faster and faster.

During the past year, a major rethink

by astronomers has led to the suggestion that the Universe may be doing just that. This remarkable conclusion is the result of combining new observational data with theoretical calculations about a range of different astronomical studies. These include not only direct measurements of the cosmic deceleration, but information about the density of matter in the Universe and the ages of galaxies. Although all of these are subject to many uncertainties and errors, cumulative evidence has led two astronomers to claim that an accelerating universe is the most plausible model. In this issue of *Nature* (page 454), James E. Gunn (Hale Observatory) and Beatrice M. Tinsley (Lick Observatory) present their case. Although they are mindful of the somewhat shabby history of the cosmological term in general relativity ("most relativists find it repulsive on principle rather than by observation") they conclude that it is probably non-zero. Collecting together all the various constraints on the cosmological parameters leads them to suggest not only that the Universe is in runaway motion, but that it is also spatially closed, like Einstein's original model.

Naturally it will await new data and the shedding of well entrenched ideas before this model of the cosmos becomes a serious contender. If this should prove to be the case then the time will have come for the physicists to take a new look at the unwelcome appendage to Einstein's general relativity and try to understand fully the nature of the mysterious cosmic repulsion.

Sir Charles Lyell

from Martin J. S. Rudwick

The Charles Lyell Centenary Symposium sponsored by the Royal Society, the Geological Society and the British Society for the History of Science was held in London on September 1–5. It also formed the sixth symposium of the International Committee on the History of the Geological Sciences (INHIGEO).

THE name of Sir Charles Lyell (1797–1875) must be familiar to every geologist, but few perhaps have actually read his classic work on the *Principles of Geology*. Likewise historians of science often refer in passing to Lyell's work as a preparation for Darwin's, without perhaps understanding fully its importance in its own right. The Charles Lyell Centenary Symposium was designed to bring geologists and historians together for

five days of intensive discussion, not only about Lyell himself, but also about his antecedents in geological science, his contemporaries and his legacy to subsequent work.

As is usual when historians of science and working scientists meet, there was at times some tension between those who see the broader historical context as all-important, and those with greater interest in the content of the scientific ideas and observations of the period. But this mingling of professional historians with special expertise in the cultural climate of 19th century science, and geologists who often have a more detailed knowledge of particular scientific problems, was generally felt to be an enriching experience on both sides. A more interesting and more important cleavage of opinion emerged during the symposium, cutting across these lines of professional affiliation. This concerned the nature and even the reality of whatever 'revolution' or 'paradigm' Lyell may be claimed to have initiated

in geology. This is a topic that has been keenly debated among historians of geology in the past few years, but which has not yet penetrated much beyond the specialist literature.

After an inaugural speech by Sir Kingsley Dunham (Institute of Geological Sciences, London), the symposium was plunged at once into the heart of this controversy by a paper urging the members to apply Lyell's own scientific principles to the historical interpretation of Lyell himself! Using Lyell's own re-writing of the history of geology as his theme, R. S. Porter (Cambridge University) urged the symposium to be 'uniformitarian' about 19th century geologists, and to reject 'catastrophist' historical accounts that see Lyell's work springing miraculously out of an earlier morass of obscurantism. Several later speakers took up this challenge, enlarging on Lyell's own view of his place in the development of geology, and relating his work to that of his predecessors and contemporaries in

Britain, Sweden, Germany, Italy, France and elsewhere.

The view that there was a sharp disjunction between Lyell and his 'catastrophist' opponents was re-stated by Lyell's most recent biographer, L. G. Wilson (University of Minnesota), but without the conceptual comparison that might have led to a fuller discussion of the precise nature of Lyell's originality. Indeed, several speakers emphasised how the different meanings of 'uniformity' in geology had often been confused by Lyell himself, and had led to continuing misunderstandings in geological debate up to the present day. As C. J. Schneer (University of New Hampshire) remarked in his final summing up, what emerged from the symposium was very much a picture of Lyell 'warts and all'—a man who could be less than generous in acknowledging publicly his debts to other scientists, and whose work was perhaps less 'revolutionary' than he and his more enthusiastic admirers believed; and yet this more balanced and human picture of the man could hardly detract from our appreciation of his achievement in helping to consolidate the methods and goals of his chosen science. J. D. Burchfield (Northern Illinois University) summarised the way in which Lyell's cherished theory of a 'steady-state' earth crumbled in the late 19th century before the onslaughts of the physicists led by Lord Kelvin; but other speakers emphasised the continuing impact that Lyell's more general approach to geology had had in regions as far apart as Germany, the USA, Japan and the Pacific.

In addition to the main sessions at Imperial College, the symposium members were able to imbibe something of the atmosphere of the scientific institutions of Lyell's day, with visits to King's College and University College London, the Geological Society, the Geological Survey (as it then was), the British Museum (Natural History) and the University of Oxford, at each of which an exhibit related to the theme of the symposium was on display. In the course of these visits, a paper by J. B. Morrell (University of Bradford) showed how Lyell's own choice of affiliations to such institutions reflected their relative value to the rising professionalism of the science of that period; while M. J. S. Rudwick (Vrije Universiteit, Amsterdam) argued that visual modes of communication in published works on geology had played a decisive role in the emergence of the science. For many members, however, the high point of the symposium was the visual re-appearance of Lyell himself (ably impersonated by the symposium secretary, J. C. Thackray of the Institute

Geological Society of London

of Geological Sciences) in the lecture theatre of the Royal Institution, where a re-enactment of extracts from his early public lectures gave a vivid demonstration of his persuasive rhetoric.

Geology is a science in which the impact of first-hand experience of particular phenomena has often been deeply influential on the theoretical development of individuals. It was therefore appropriate that the symposium included two field trips, before and after the main meeting, to classic geological areas that were closely associated with Lyell: the Isle of Wight and the New Forest, where he spent his childhood and early manhood, and eastern Scotland from Berwickshire to Angus, where he was born and where he later did some of his best early research. Here perhaps the high point was the party's reception by Lady Lyell and Lord Lyell at the family home of Kinnordy House,

where books and papers from Charles Lyell's library were on display.

The symposium was highly successful in re-creating the historical context in which Lyell and his contemporaries strove to make geology a science with firmly established methods and clearly defined cognitive goals; and the widespread interest of geologists in this achievement is surely evidence of its continuing influence in the science. The superbly smooth running of the symposium, due chiefly to the chairman of the organising committee, D. A. Bassett (National Museum of Wales, Aberystwyth), might seem to make any criticism ungracious. But as R. Hooykaas (Rijksuniversiteit Utrecht and Vice-President (Europe) of INHIGEO) pointed out in his final vote of thanks, if English is to be used—as it is nowadays—as the common language of science and scholarship at international meetings, those

who have English as their native tongue must learn to be more considerate towards those who are less fortunate in this respect. As at other such conferences, too many papers by British and American speakers were delivered at ultra-high velocity and with low signal-to-noise ratio. Such thoughtlessness is hardly fair on the rest of the world. □

Alpha-clustering in nuclei

from P. E. Hodgson

THERE are now very many lines of evidence that show that the nucleons inside the nucleus tend to form clusters that persist long enough to affect many nuclear properties. The most likely form of cluster is the alpha particle because of its high symmetry and binding energy, and much evidence for the presence of alpha clusters comes from nuclear structure calculations and from measurements of the cross sections of many nuclear reactions.

The structure calculations of Brink and Castro (*Nature*, **248**, 280; 1974) showed that when nuclear matter is reduced to about one-third of its density at the centre of a heavy nucleus it tends to coalesce into alpha clusters. This suggests that in the outer regions of the nucleus, where the density is low, it is very likely that alpha clusters will be found.

In the case of light nuclei the Hartree-Fock calculations of the nuclear density show very directly the regions of maximum density, three for carbon, four for oxygen, five for neon and so on, and this suggests that these nuclei are made up of clusters of nucleons resembling alpha particles.

The familiar process of alpha decay is a very direct indication that alpha particles are to be found in nuclei. Theories have been developed that express the probability of alpha decay as the product of one factor representing the probability of an alpha particle being formed on the nuclear surface and a second factor giving the probability that it will tunnel through the potential barrier and be emitted. These theories are able to account for the very wide range of alpha decay lifetimes that occur in natural and artificial radioactive isotopes.

Many nuclear reactions also provide direct evidence of alpha clusters in nuclei. Among the most widely studied are the alpha-transfer reactions, in which an alpha particle is either removed from or added to the nucleus. Many such reactions have been studied, such as the ($^6\text{Li}, d$), ($^7\text{Li}, t$) and ($^{16}\text{O}, ^{12}\text{C}$) reactions and their inverses (*Nature*, **252**, 270; 1974). The cross sections of these reactions can be calculated by the same distorted wave theory as the one-nucleon transfer reactions by treating the transferred

particle as a single entity. On the whole this theory is very successful and allows us to calculate the probabilities of alpha formation in various states. These are the alpha-particle spectroscopic factors, which can be compared with detailed nuclear structure calculations (*Nature*, **255**, 373; 1975).

Other nuclear reactions that tell us about alpha clusters are the ($\alpha, 2\alpha$) and (p, α) reactions in which an alpha particle or a proton knocks an alpha particle out of the nucleus, but these are not so easy to treat theoretically and so have not yet given very precise information.

The (p, α) and (n, α) reactions at medium energies can give useful information about alpha clusters, since they often have a component due to the pre-equilibrium process, and if this is analysed it gives an estimate of the preformation probability of the alpha clusters (*Nature*, **245**, 12; 1973).

Reactions caused by pions and kaons have also been used to probe alpha structure, and many studies at low and high energies have provided some indications that alpha particles are present in the nucleus, and can be knocked out in favourable circumstances (*Nature*, **248**, 105; 1974; **249**, 616; 1974; **254**, 561; 1975).

It is very useful to have a clearer model of the behaviour of these alpha particles in the nucleus. Of course we know that all the phenomena mentioned can, at least in principle, be accounted for entirely in terms of the nucleons, without explicit mention of alpha particles. But nevertheless it is useful to think in terms of alpha clusters since they form an obvious physical feature of the nucleus, and if we can find a theory expressed in terms of alpha particles it will certainly be very much simpler than the corresponding description in terms of nucleons alone. We have to pay for the simplicity by some loss of precision, but this may well be acceptable if it gives us a simple model yielding physical insight into many phenomena and a way of calculating many features to fair accuracy.

Such a model can easily be constructed by analogy with the simple nucleon shell model. It is notable that all the reaction phenomena that can be understood by the nucleon shell model, in particular the optical model analysis of elastic scattering and of the resonances due to coupling to inelastic channels as well as the nucleon transfer data, are paralleled by similar phenomena for alpha particles.

This suggests that alpha-clustering phenomena can be understood by grafting on to the nucleon shell model the possibility that nucleons in outer orbits can combine to form alpha particles having a life long enough for their influence to be felt. These orbits have the quantum numbers that can easily be calculated from those of the constituent

Table 1 Theoretical and experimental alpha widths for ^{16}O

5 ⁻	700	≈ 2000	1.539
7 ⁻	750	776	1.668

Data from Buck, Dover and Vary (1975).

nucleons and alpha transfers can take place to and from these alpha orbits just as nucleon transfers can take place to and from the nucleon orbits.

According to this model the alpha particles are bound by an alpha-core potential, whose eigenvalues and eigenfunctions give the centroid energies and wavefunctions of the alpha states, just as for the nucleons. It is simplest to assume that this potential has the Saxon-Woods form,

$$V(r) = V_0 / \{1 + \exp[(r-R)/a]\}$$

where R and a are radius and diffuseness parameters. Once these parameters are fixed the depth of the potential V_0 is determined by the alpha-transfer data. The only remaining parameter, the probability of alpha formation, is given by the spectroscopic factor for alpha-transfer reactions. This parameter is the only one in the model that has nothing corresponding to it in the analogous nucleon case.

Many studies of nucleon transfer reactions (*Nature*, **245**, 74; 1973) showed that the nucleon potential determined from an overall analysis of many reactions varies in a systematic way from nucleus to nucleus, and preliminary analysis of alpha-transfer reactions showed that this is also the case for the alpha potentials. This model has been applied to the alpha particle resonant states in medium weight nuclei and it is found that the energies and ordering of the eigenstates are qualitatively in accord with experiment.

A detailed study of this model as applied to light nuclei has been made by Buck, Dover and Vary (*Phys. Rev.*, **C11**, 1803; 1975). They determined the alpha potential by folding the densities of the nuclear core and the alpha particle

$$V(r) = -(2\pi\hbar^2/M)f \int \rho_A(r-r')\rho_B(r')dr'$$

where f is a real depth parameter. The densities ρ_A and ρ_B were taken from electron scattering analyses. It turns out that this potential has several advantages over the Saxon-Woods potential; in particular it can reproduce the energies of the states of low-lying rotational bands with essentially the same depth parameter.

Many studies of alpha-transfer reactions

(*Nature*, **252**, 632; 1974) have shown that they preferentially populate the rotational bands in light nuclei. This strongly indicates that these states have core + alpha structure, and it is therefore natural to interpret such states as eigenstates of the above potential.

Buck *et al.* therefore applied their model to calculate the energy spectra of the $K^\pi = 0^+$ and 0^- bands in ^{16}O and ^{20}Ne , and the results for ^{16}O are shown in the figure. The parameter f was adjusted for each band, and the model then gives a good overall fit to the energies of all the states in that band. Since the widths are very strongly energy dependent, f was adjusted for each state to give the widths shown in Table 1. The required changes in f from the mean (band) values are only a few per cent. The correspondence between the measured and calculated widths indicates the qualitative reliability of the model. Since the calculated widths are very sensitive to the addition of an imaginary part to the depth parameter f , it is not correct to interpret as spectroscopic factors the ratios of experimental to calculated widths in this table.

The potentials give the alpha-cluster wavefunctions, and hence the alpha-core separations and root mean square (RMS) radii $\langle r^2 \rangle^{1/2}$ given for the ground state band of ^{20}Ne in Table 2. The values labelled $\rho^{(1)}$ and $\rho^{(2)}$ are obtained by Mosely and Fortune and by Arima and Yoshida respectively using Saxon-Woods potentials to generate the alpha-cluster wavefunctions, and $\rho^{(3)}$ is obtained from the Hartree-Fock calculations of Lee and Cusson. The model also gives values of $\langle r^2 \rangle^{1/2}$ that agree well with the empirical value of 2.9 fm given by Elton. All these models predict an anticentrifugal stretching effect. That is, the higher spin states correspond to a lower value of ρ and hence a smaller $\langle r^2 \rangle^{1/2}$. In the folding model this does not require a change in the radius of the potential itself.

As a final test of the model, Buck *et al.* calculate the electromagnetic transition rates between the states of the ground state band of ^{20}Ne , and these are compared

in Table 3 with the data and with shell model and rotational model calculations. In this calculation the effective charge was adjusted to $e_{\text{eff}} = 1.245e$ and gives values of $B(E2)$ quite close to those of the complete shell-model calculation which used $e_{\text{eff}} = 1.583$.

These results show that the alpha cluster model is able to give a good overall account of the energies and widths of the states of ^{16}O and ^{20}Ne , and the alpha-core separations, RMS radii and electromagnetic transition rates. It has considerable predictive power, since all this information can be calculated as soon as the depth parameter is fixed by comparison with the energy of a single state. It remains to be seen to what extent it will also be successful for other nuclei. It would be particularly interesting to use the alpha-cluster wavefunctions in analyses of alpha-transfer reactions, and hence obtain information on the alpha-

Comparison between the theoretical and experimental energies of the $K^\pi = 0^+$ and 0^- rotational bands in ^{16}O . The theoretical energies are calculated from an alpha- ^{12}C folded potential with depth parameter $f = 1.425$ fm for the 0^+ band and $\bar{f} = 1.55$ fm for the 0^- band. The arrow indicates the energy of the $\alpha + ^{12}\text{C}$ threshold in ^{16}O . (Buck, Dover and Vary, 1975).

Table 2 Comparison of various calculated values of the alpha-core separation and RMS radii for the ground state band of ^{20}Ne

J^π	ρ	$\rho^{(1)}$	$\rho^{(2)}$	$\rho^{(3)}$	$\langle r^2 \rangle^{1/2}$

spectroscopic factors and formation probabilities, which could be compared with values obtained in other ways. \square

Immunoglobulin surprises

from C. C. F. Blake

THE recent X-ray determinations of the structures of immunoglobulin Fab's and Bence-Jones proteins have enabled the crystallographers involved to correlate the structure with existing data, and at the same time to extract new and unsuspected information. Poljak in a recent review in *Nature* (**256**, 373; 1975) shows how satisfyingly the large body of chemical and immunogenetic data can be brought together in the light of the molecular structure to provide a unified view of the immunoglobulins.

In accord with this unified view Padlan and Davies (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 819; 1975) have elegantly analysed the structural variability in the combining site. They compared the structures of the V_H , V_L and C_L domains of the murine α, κ Fab McPC603 and V_L domain of the kappa-type Bence-Jones protein REI, using an interesting variation of the diagonal plot. In its more usual form the distances R_{ij} between the i th and j th atom in a molecule are plotted on a diagonal matrix against residue number and contoured at constant separation distance. Secondary structural elements produce characteristic forms of the contour surface and the whole plot reduces the three-dimensional structure to a comprehensible two-dimensional form. In the variation proposed by Padlan and Davies, appropriate for comparing similar structures, the quantities $R_{ij}^A - R_{ij}^B$ are plotted against residue numbers; where R_{ij}^A and R_{ij}^B are the corresponding interatomic distances in the two immunoglobulin domains A and B that are being compared. These difference plots show a number of interesting features, including the close structural resemblance between the V and C domains, but undoubtedly the most important is the concentration of structural differences in the hypervariable regions of the V domains. Padlan and Davies make a most telling correlation by plotting the 'average relative displacement' which represents the change in average distance between a particular residue and all the 'framework' residues in the structure from one domain to the other, against residue number. This plot bears a quite remarkable similarity to the plots of sequence variability and demonstrates very clearly that the hypervariability of sequence is paralleled by an equivalent structural variability. Thus the hyper-

variable regions, by causing insertions and deletions that change the size and shape of the combining site and amino acid substitutions that alter its chemical nature, provide the immunoglobulin molecule with an almost unlimited potential for antigen binding and antibody diversity within an otherwise constant molecular framework.

Although it is encouraging to see this model emerge from the X-ray studies, it was of course already implicit from the studies of sequence constancy, variability and hypervariability. By contrast an aspect of immunoglobulin structure that could not have been foreseen is the subject of a paper by Edmundson *et al.* (*Biochemistry*, **14**, 3953; 1975). Now that the X-ray studies have shown a structural homology between the V and C domains, it is clear that all the domains in the γ globulins have been derived by divergence from a single common ancestral gene. Edmundson and his colleagues have addressed themselves to the most important question in this context: what changes have led to the functional differentiation of the constant and variable domains? The X-ray studies have shown that the basic immunoglobulin fold has a four-stranded and a three-stranded β sheet. In the Fab's and Bence-Jones proteins the constant domains pair through the four-stranded sheets with hydrophobic interactions in a solvent-free interface, while in the variable domains the three-chain layers face each other across a solvent-filled channel that forms the combining site. On this basis Edmundson and his colleagues suggest that the V and C domains are rotational allomers and show that 38 pairs of homologous residues in the two domains are related by a rotation of 163° – 167° about an axis that passes through the intrachain disulphide bridges near the centre of each domain. They also argue that the sequence patterns in the β sheet correlate with this model. For example, in the C domain of the Mcg Bence-Jones protein the normally alternating pattern of polar and apolar residues is broken in the four-chain layers by substitution of hydrophobic residues for hydrophilic residues at the sites of interaction in the C_1 – C_2 interface. Similarly in the V domains the pattern is interrupted in the three-chain layers by substitution of aromatic for aliphatic polar residues in positions important for the maintenance of the geometry of the binding site. Edmundson believes that these genetic changes have led to rotational allomerism of the V and C domains such that homologous regions in the two domains perform different functions, and concludes that this unusual event was of critical importance in the evolution of the immunoglobulins. \square

Many models for cell growth and development

The 8th Harden Conference—Control Systems in Normal and Malignant Cells—was held at Wye, UK, on September 14–19.

from Robert Shields

THE most striking impression left by the conference is not that there are too few model systems to study growth regulation but too many. Only a few of these are easy to manipulate *in vitro* but unfortunately these are often the least interesting biologically.

Perhaps the most exciting system which is just beginning to be amenable to *in vitro* manipulation is provided by teratocarcinomas. For some time it has been claimed that teratocarcinomas contain pluripotent mouse embryo cells (termed embryonal carcinoma) but convincing evidence that this was so has so far been lacking. In an elegant demonstration R. L. Gardiner (Oxford University) showed that chimaeric mice could be obtained when the inner cell mass of mouse blastocyst was replaced by clumps of embryonal carcinoma which had been grown *in vitro*. The animals were chimaeric not only for coat colouring but also for isozyme markers, proving conclusively that embryonal carcinoma cells are truly pluripotent. The availability of large amounts of what is essentially embryonic material opens up a whole range of intriguing avenues for study using methods described by other speakers.

One of the most fascinating embryological problems is that of how position in the early embryo influences subsequent development. The great problem with this kind of study is to mark genetically an early embryo cell in such a way that its progeny can be recognised at later stages. Potentially this might be done by making metabolic mutants of embryonal carcinoma cells *in vitro* and transferring these to the blastocyst. These cells could survive in the developing embryo if they were capable of metabolic cooperation and their descendants could be recognised later in development. Work described by J. D. Pitts (University of Glasgow) suggests that metabolic cooperation takes place in many cell types *in vitro*, even between cells from species as diverse as *Xenopus* and hamster. Experiments with metabolically defective embryonal carcinoma cells might prove that similar events occur *in vivo*.

A promising *in vitro* approach to developmental processes using Friend

erythroleukaemic cells was described by P. Harrison (University of Glasgow). These cells appear to be arrested pro-erythroblasts and can be persuaded to differentiate by addition of DMSO. This provides valuable information on the timing of gene transcription and translation since globin messenger sequences can be detected using complementary DNA probes. By making mutant cells unable to differentiate and fusing these with other cells and looking for complementation it is proving possible to dissect genetically the processes that control haemoglobin production.

The sessions on cell growth control were predictably dominated by the search for the message that transmits signals received at the cell surface to the internal machinery of the cell. The current dogma is that macromolecular mitogens act at the cell membrane and do not enter the cell. As J. Kay (University of Sussex) pointed out, however, at least one macromolecule, ricin toxin, exerts its effect by entering the cell, so even the concept of surface receptors may need re-examination. A further complication is introduced by heterogeneity of mitogens and of cell types. Lymphocyte workers have often congratulated themselves on being able to work with well defined mitogens; however, the talk by F. Melchers (Institute for Immunology, Basel) showed that this is often paid for by using heterogeneous cell types in different stages of development. On the other hand, those working with cultured cells can work with a cloned cell type but have to put up with a heterogeneous mitogen, serum. In spite of this, one of the striking things about the action of different mitogens on many different cells is that the metabolic processes stimulated are very similar; what goes for the fibroblast goes for the lymphocyte. The problem is to sort out which metabolic changes cause and which are associated with cell growth.

Using pig T lymphocytes, M. J. Crumpton (MRC National Institute for Medical Research, Mill Hill) showed a close correlation between phosphatidylinositol (PI) turnover and mitogenic stimulation with a whole series of mitogenic and non-mitogenic lectins, however PI turnover was not increased by phorbol ester which is a potent mitogenic agent, showing that PI turnover is not the primary mitogenic event nor is it a necessary signal for cell proliferation. Furthermore a limited degree of lymphocyte stimulation can be produced by the calcium ionophore which also stimulates PI turnover, showing that PI turnover may be a consequence of increased calcium flux into the cell.

Another early event in the induction of cell proliferation is the stimulation of potassium entry by the Na^+/K^+

ATPase. Using cultured 3T3 cells, E. Rozengurt (Imperial Cancer Research Fund, London), could separate the serum-induced stimulation of potassium transport from the increase in phosphate transport and also from the concomitant fall in cyclic AMP levels. The role of cyclic GMP (if any) in the control of growth is still obscure. Data presented by L. Jimenez de Asua (ICRF, London) showed that different stimuli can raise cyclic GMP in 3T3 cells to the same level and yet have very different degrees of mitogenic activity. This suggests that cyclic GMP is unlikely to be the sole trigger for increased growth.

Not all relationships between the cell's interior and the environment need be conducted with chemical messages, physical interaction is also feasible, possibly through proteins which span the cell membrane. Untransformed cells display a protein of about 250,000 daltons on their surfaces, and this protein disappears when the cell is transformed. By making fluorescent antisera to this surface protein A. Vaheri (Helsinki) was able to show that this protein codistributed with actin-containing filaments which lie under the cell membrane. Furthermore, the actin filaments and surface protein disappeared together when the cell was transformed. These results suggest that the surface protein may be linked directly or indirectly to actin-containing structures in the cytoplasm. □

Waxworks for plate tectonics

from Peter J. Smith

AN oceanic ridge and the transform faults that divide and offset it are approximately orthogonal, irrespective of the overall trend of the ridge with respect to the plates on either side. The reasons for this particular geometry are still not entirely clear, or at least not beyond dispute. Most of the explanations put forward so far have involved a minimum energy criterion; in other words, it is generally assumed that the final ridge-fault configuration is that offering least resistance to plate separation. But this implies that when plates diverge the resistive forces per unit length of ridge crest are much greater than those per unit length of transform fault, an inference which is apparently inconsistent with the observation that the seismic energy released at ridge crests is no greater than that released along transform faults.

In an attempt to resolve this dilemma, Lachenbruch and Thompson (*Earth planet. Sci. Lett.*, **15**, 116; 1972)

suggested that the region in which the seismic energy is released and that chiefly responsible for the resistance to plate motion may not coincide. Specifically, they envisaged that whereas the seismic energy is released at the ridge crest in the crust which is continually breaking, the dominant resistive force is the highly viscous fluid in an intrusion zone below. But as Oldenburg and Brune (*J. geophys. Res.*, **80**, 2575; 1975) now point out, the large resistive forces invoked in this and similar models are a consequence of regarding the lithosphere as a slab of constant thickness and the intrusion zone as a narrow vertical channel beneath the ridge crest—a situation in which the plate thickness is much greater than the width of the intrusive channel. Their own model, by contrast, suggests that this condition may not obtain.

But whereas the Lachenbruch-Thompson model is conceptual, Oldenburg and Brune have constructed a real physical system. They have a tray of melted wax which is cooled until a film of solidified wax has formed between one end of the tray and a moveable paddle. When the paddle is pulled at constant velocity away from the solidified surface in which an initial zone of weakness has been produced, a miniature system of ridge segments and perpendicular transform faults is "easily attainable"—a remarkable imitation of a phenomenon discovered less than 20 years ago, using apparatus which could in principle have been constructed more than 2,000 years ago.

Whether this physical model leads to conclusions that are more or less applicable to the real Earth than those derived from its more theoretical predecessors remains to be seen. In the meantime, however, Oldenburg and Brune believe that it can provide valuable insight into oceanic ridge processes because it can be observed directly on a reasonable time scale, because quantitative measurements may be made and because the properties of the system may be varied and their effects noted. It is a simple matter, for example, to measure the thickness of the solidified surface film of wax at any point in the tray; and 'plate' thickness thus obtained is always found to increase as the square root of distance from the 'ridge'. Clearly this direct result conflicts with the constant thickness assumption built into the Lachenbruch-Thompson and other analyses.

If the wax is to be believed, the idea of high resistive forces at ridge crests may also have to be discarded, for observation shows that the ratio of the thickness of the 'plate' to the width of the intrusion zone can be quite small in the vicinity of the 'ridge crest'.

Moreover, order of magnitude calculations by Oldenburg and Brune suggest that the resistive forces per unit length of 'transform fault' are at least two, and possibly as many as four, orders of magnitude greater than those per unit length of 'spreading ridge'. Because so little is known about the physical and dynamic properties of Earth materials at depth, it is difficult to carry out comparable calculations for the real Earth. Nevertheless, assuming that the top few kilometres of the ridge crest act as a vertical channel and that the region below (defined now by a lithosphere increasing in thickness away from the ridge) is a zone of partial melt with Newtonian viscosity, Oldenburg and Brune estimate that the resistive forces along a transform fault are probably about an order of magnitude greater than the viscous forces acting beneath the few kilometres thick crust at a ridge crest of the same length.

Although such calculations must be treated with reserve, they do suggest that previous estimates of the viscous forces at ridge crests may be too high because of an inappropriate geometry assumed for the intrusion zone. Maintenance of the minimum energy criterion for orthogonal spreading would therefore require a large resistive contribution from the upper few kilometres of the ridge crest, thus restoring the seismic energy release contradiction. The only way out would seem to be to abandon the minimum energy assumption for the Earth, just as observation and calculation show it to be inapplicable to the wax model.

Instead, what seems to be crucial in producing the orthogonal pattern is the particular combination of physical properties involved. The wax model does not always lead to perpendicular ridge-fault spreading; it is necessary to use the 'right' kind of wax, and to adjust the temperature of the wax, the rate of surface cooling and the rate of spreading. The wax experiments show, however, that as far as the material is concerned the critical conditions for formation of the orthogonal pattern may be summarised as a single dimensionless parameter G , the ratio of the shear strength of the solid to the resistive stresses along the transform fault. The pattern may only be maintained as long as $G > 1$. Once this criterion is satisfied, the development of the pattern is then determined by the symmetry of the applied stress field and the ability of the wax to fracture in a brittle manner under the applied stresses. In the Earth, both symmetry and brittle fracture are assured. G is more difficult to assess, but preliminary estimates suggest that it may be as high as 30. □

Insect development

A symposium on Insect Development was held by the Royal Entomological Society in London on September 18–19.

from our *Insect Physiology Correspondent*

THE biennial symposia organised by the Royal Entomological Society of London, which have now been running for fifteen years, are unusual in that their purpose is primarily educational: to provide an opportunity for entomologists to learn in comparatively simple terms, from researchers at the fringes of knowledge, what is going on in a given field of study. The latest symposium was organised by P. A. Lawrence around the topic of the genesis of pattern development at all stages from egg to adult. Of the twelve contributors more than half came from overseas. The meeting, with an attendance not far short of 200, attracted students of growth outside the insect world and they were gratified to learn that insect development was nothing like so mosaical as they appear to have believed.

H. A. Schneiderman (University of California, Irvine) gave a general survey of the wide range of work going on in the experimental analysis of determination in the cortical cytoplasm and in the imaginal disks of *Drosophila*. He did not carry all the audience with him in his distinction between 'specification' for cell commitments which are heritable and 'determination' for commitments which are non-heritable. K. Sander (University of Freiburg) provided an introduction to insect embryology with emphasis on the nature of movements in the embryo. Evidence from exceptionally clear time-lapse photography indicates that the centrifugal movements of the nuclei at cleavage are effected by tension generated by fibrils of the nuclear asters extending to the cortex; and that the later invaginations result from tension on the blastoderm by cells in the yolk. Using a somewhat different terminology from Schneiderman, K. Kalthoff (University of Freiburg) spoke of cell determination and differentiation, but of pattern specification and realisation. Recent work by the Freiburg group has tended to support a gradient model of determination in the cortical plasma of *Drosophila*, with some evidence that masked messenger RNA may be the chemical agent. But a generalised interpretation of these observations suggested a temporal progression from a gradient state to a mosaic state, the timing varying in different insects and

being most precocious in the highly evolved forms. This sounded very much like a modernised expression of the Seidel view of things. K. Illmensee (Institute for Cancer Research, Philadelphia) had shown that genetically labelled cleavage nuclei and blastoderm nuclei from all parts of the *Drosophila* egg could contribute to any somatic structures and even to the germ line, and that the cytoplasm of the oosome could induce germ cells elsewhere.

Turning to the imaginal disks of *Drosophila*, W. Gehring (University of Basel) described the results of injection of dispersions of genetically labelled cells into wild type hosts, and their ultimate differentiation. Whereas there was already some determination at the two ends of the germ band, at the imaginal disk stage the cells were biochemically distinct. This was well seen in the aldehyde oxidase activity acquired by the antennal disk as contrasted with the wholly negative eye disk. R. Nöthiger (University of Zurich) illustrated the immense value of clonal analysis in the study of imaginal disks. Mutants induced by X-irradiation, followed by mitotic recombination, at different points in development, can demonstrate the

timing of decision taking, and the stability of the resulting determination. J. R. S. Whittle (University of Sussex) emphasised the caution needed in the use of mutants in morphogenetic studies where, for example, biochemical abnormalities could provoke pleiotropic defects in growth. P. A. Lawrence (University of Cambridge) described the important results of Garcia-Bellido and his colleagues in Madrid in the definition of 'compartments' of the integument derived from the lineage of single cells or groups of cells and visualised by X-ray-induced mitotic recombination. Even when using such mutant cells in a polyclone which far outgrows the surrounding cells, the mutant cells never intrude beyond the compartment boundary—such as exists in the longitudinal mid-line of the *Drosophila* wing or at the intersegmental boundary of the *Oncopeltus* abdomen. Recent evidence obtained in Cambridge has made clear that this remarkable restriction depends on a failure of mutual intercellular adhesion with cells outside the compartment, a property carried by special genes. The results of further studies of the significance of this new genetic unit of development will be awaited with great interest. □

Plant collections and conservation

Recommendations for the preservation of endangered plants have come from an international conference held at the Royal Botanic Gardens, Kew on September 2–6. Participants from 28 countries, meeting to consider the function of living plant collections in conservation and related research and public education, produced some resolutions calling for early action.

They include the following:

- A worldwide network of nature reserves and gardens oriented towards conservation should be established, and institutions in temperate countries should provide technical aid and personnel through the auspices of the International Union for Conservation of Nature and Natural Resources.
- Special attention should be given to the conservation of threatened floras of islands and areas with Mediterranean and similar climates, where many endemic species are endangered by human activities.
- Institutions with plant collections are recommended to give

priority to the local flora, so as to benefit from available specialist knowledge and to reduce the need for simulated climatic conditions. In this way institutions will be best able to advise and educate specialists and the public about the conservation of indigenous species.

- All governments are urged to ratify the Convention on International Trade in Endangered Species of Wild Fauna and Flora as soon as possible.
- Wherever possible, all living plant collections grown for conservation purposes should also be stored in the form of seeds.
- The propagation of rare and endangered species should be actively pursued by botanic gardens and other bodies maintaining living plant collections, and, when necessary, they should be supported by conservation or other appropriate organisations. Special attention should be given to economic plants and their wild relatives and to plants which may have commercial value.

Letters from Einstein to de Sitter on the nature of the Universe

Carla Kahn & Franz Kahn*

The correspondence between Einstein and de Sitter during 1916 and 1918, recently discovered in the archives of the Sterrewacht at Leiden provides a fascinating glimpse of the thinking of the two principal progenitors of modern cosmology.

In August 1974, when the Sterrewacht in Leiden moved from the buildings which it had occupied since 1861, its archives moved with it. During the time of the removal Professor van de Hulst received a letter from Princeton. Miss Helen Dukas, Einstein's former secretary, was going through Einstein's papers, and had found some letters from de Sitter. de Sitter, who was one of the greatest directors of the Sterrewacht, was also one of the best astronomers of his time. It was thought that there might be corresponding letters from Einstein in the archives of the Sterrewacht.

In the chaos of the move from the old Observatory it was not possible to look for the Einstein correspondence immediately. It was not until we, a visiting professor of astrophysics and his wife, arrived at the Sterrewacht at about the time when the move was over, that a serious search was begun. It was suggested that one of us (C.V.K.) might index the archives, partly with a view to the possibility of finding the letters from Einstein.

Very little had been done with the papers in the past 25 years, and there was no way of finding interesting material, except by searching through all the storage boxes. In fact it was only at the thirtieth box that anything appeared which could be connected with the Einstein letters, but when they did turn up there were seventeen items of correspondence. Some were postcards and some longer letters. All but one were written by hand, and dated between 1916 and 1918. Some had been sent at intervals of about a week, and even so had obviously left time for a reply to be dispatched in between. The postal system seems to have been rather better than it is now, even though Germany was at war.

Most of the letters contained discussions of the theory of general relativity. An important purpose of Einstein's contact with de Sitter was to get this work known in England. In 1915 Einstein's first paper on the subject had appeared in Germany. But there was no communication between Germany and England at the time, and so de Sitter eventually published two long articles on relativity in the *Monthly Notices of the Royal Astronomical Society*. In preparing them he must have been stimulated to think about the subject himself and to make his own contributions. In his letters and postcards Einstein throws an interesting light on his own reactions to de Sitter's ideas.

At that time Einstein included interactions of two kinds in his theory. The first was gravitational: each mass causes a distortion of the space around itself and so affects the motion of other masses. A significant difference between Newton's laws of

gravitation and those of Einstein would only occur when very large differences of gravitational potential were involved, so that a particle moving in such regions would acquire a speed comparable to that of light. Such large potentials are likely to occur only in astronomical situations, which explains the current interest of relativists in black holes. But sixty years ago no one believed in such objects, and they are still somewhat controversial. So Einstein had to turn to the large scale properties of the Universe to find a promising application for his theory. In any case he seems to have been attracted by the age-old problem of whether space is infinite or finite, either of which seems hard to accept. To make a model of the Universe in equilibrium he needed another kind of interaction, in addition to gravitation, for with gravity alone he knew that there could be no static configurations. The general theory of relativity can be formulated so as to allow for the existence of another interaction, the cosmical repulsion. This was described in terms of the so-called Λ term, but the exact value of Λ was not predicted, and could well have been zero. (Nowadays most

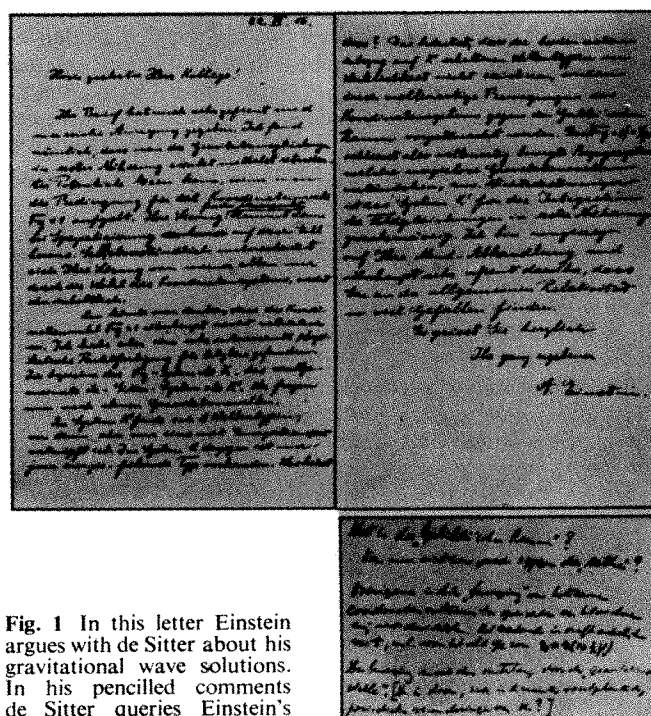

Fig. 1 In this letter Einstein argues with de Sitter about his gravitational wave solutions. In his pencilled comments de Sitter queries Einstein's opinions.

* Address: Sterrewacht, Leiden; present address: Astronomy Department, The University, Manchester M13 9PL, UK.

This article was first published in Dutch in *Natuuren Techniek*, May 1975.

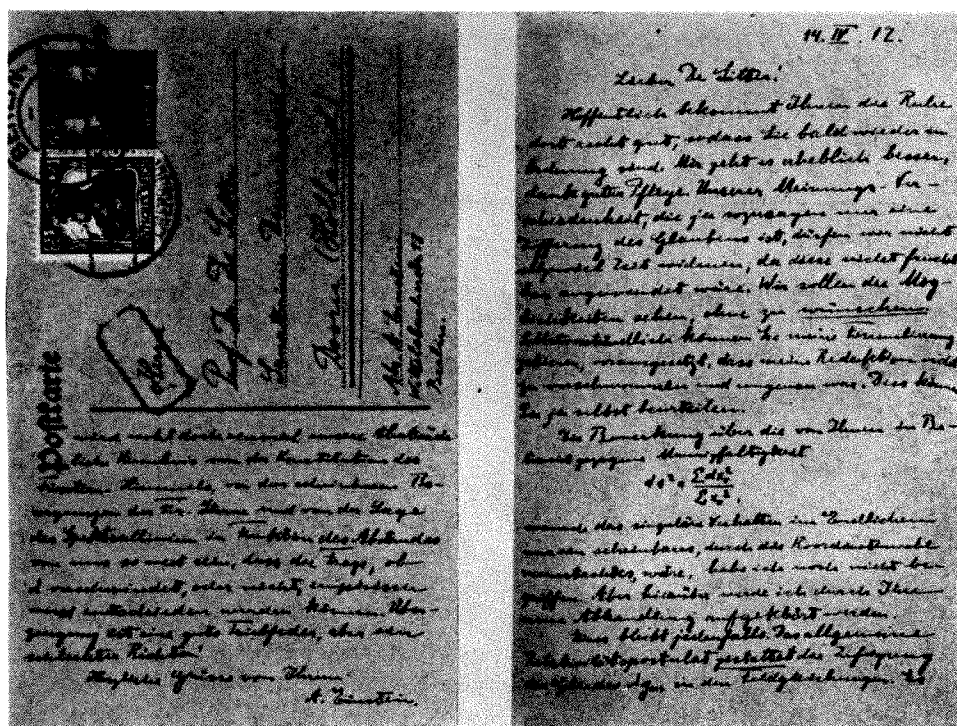

Fig. 2 Einstein expresses the view that one day our understanding of the system of stars will be good enough to determine whether Λ vanishes or not. He concludes "Conviction is a good mainspring, but a bad regulator".

relativists believe, as Einstein did eventually, that Λ is in fact zero.) But with a Λ term it was possible to balance the gravitational self attraction of the matter in the Universe, provided Λ was equal to $(4\pi/3)G\bar{\rho}$, where $\bar{\rho}$ is the mean mass density in the Universe. Naturally one has first to find out what $\bar{\rho}$ is; we shall return to this point later.

The earliest letter in the archives (dated June 22, 1916) deals with the problem of gravitational waves. de Sitter had found that there were three kinds of wave: but Einstein commented that only one kind transported energy. "What does this mean?", he asks. "This signifies that the two former types of wave . . . do not exist in reality", and he goes on to say that the waves disappear when he uses a different coordinate system, which he calls "galilean space", to express his physics.

de Sitter was not happy about this idea. In a pencilled comment he asks: "What is 'galilean space'? Can one not equally say 'the ether'?" Later he concludes that the type of motion he discovered must arise through what he called a gravitational wave.

Two more letters from Einstein continue the argument, but really take it no further. Who was right? If a physicist nowadays comes across a wave-like disturbance without energy, then he immediately suspects that the system carrying the wave is unstable. Years later Lemaître in fact constructed a model universe (with a Λ term) which begins in equilibrium but moves away from it because the equilibrium is unstable. It looks as though de Sitter saw a glimpse of this—and perhaps more—when he was thinking about gravitational waves. But he could not convince Einstein.

There then follow a letter and a card, written in November 1916 and January 1917, respectively. In the letter Einstein speculates at length on the problem of Mach's principle; does the inertia of a given mass depend on the other masses in the Universe, and if so how? This kind of question has been much discussed in the past 20 years or so, but de Sitter seems not to have been greatly interested in it. At the end of his letter Einstein says: "I do not demand in any way that you should share my curiosity". The subject does not occur again in the correspondence.

The postcard is not about scientific matters at all. "It is good of you" Einstein writes "that you are throwing a bridge over this abyss of misunderstanding. With this card you will receive the reprint you asked for, plus some others, for the colleague.

When peace returns I shall write to him . . .". The colleague was presumably Eddington and the abyss the war; Einstein sensibly does not mention him by name in case the German censor read this card.

The following post card was sent on February 2 of that year. Again there is not much science, but rather plaintively Einstein remarks: "There has been no progress with the possibility for a reappointment P., and this looks suspicious to me. There must be some intrigue at work. Naturally I shall hear nothing about it before it is too late".

He was right, for in his next letter (March 12) Einstein writes " . . . it is dreadful that they elected M. rather than K. to Potsdam, in spite of the proposal by the Academy . . . It is not clear which powers are responsible. One suspects Seliger.

"Now to our business!" The business was to construct a model for the Universe, and to tie it to some observations. Einstein's starting point was the mass density in space, as determined from star counts. He took the value $\bar{\rho} = 10^{-22} \text{ g cm}^{-3}$; from this it follows by fairly general arguments that the length scale of the Universe must be about $c/\sqrt{(4\pi G\bar{\rho})}$ if $\bar{\rho}$ is representative of all space. Einstein derives a radius $R = 10^7$ light years for the Universe, "whereas", he says, "we see to a distance of about 10^4 light years". Of course we know now that the numbers were bad estimates. The density $\bar{\rho}$ would have referred to the space in the disk of our Galaxy (and even so $10^{-22} \text{ g cm}^{-3}$ is about thirty times larger than the value astronomers have determined now). The density averaged over the Universe is many orders of magnitude smaller, and our present value for the radius of the Universe consequently much larger. Finally the distance "to which we see", at least in the plane of the Galaxy, is restricted by the obscuration due to interstellar dust, and has little to do with the Universe at large.

Einstein was uneasy about the results of his investigation. "I compare space to a cloth . . . one can observe a certain portion . . . we speculate how to extrapolate the cloth, what holds its tangential tension in equilibrium . . . whether it is infinitely extended, or finite and closed. Heine has given an answer in a poem, 'and an idiot expects an answer'". And then he looks forward to his next meeting with de Sitter in Leiden. Now, almost 60 years later, we astronomical "idiots" are still waiting for the answer.

A few days later (March 24) Einstein wrote again. de Sitter had developed a model for the Universe, but Einstein did not

times one can put a rigid circular hoop into your Universe which has no place in it at time $t = 0$ ". The 'Big Bang' evidently did not appeal to him.

But he accepts it in a letter one week later (June 22) in which he gives a geometrical argument to explain why the instant of the Big Bang is special. "This point is thus *de facto* preferred . . . Naturally this does not constitute a disproof, but the circumstance irritates me".

There are several further communications from Einstein after this letter, but they are concerned more with details than with principles.

There are also less scientific parts of the letters. de Sitter and Einstein seem to vie with each other in describing their ill-health; in fact most of the letters are addressed to de Sitter at a sanatorium. Together with this correspondence there were some letters from Eddington, who was Secretary of the Royal Astronomical Society at the time. They concern the papers which de Sitter had written on general relativity. The RAS eventually published them, but at first Eddington's letters were somewhat cool. You understand, he wrote, that every paper published by the RAS has to be sent to a referee. (He would of course have been quite qualified to referee them himself.) We are having trouble with the printers, the paper is longer than we normally print and so on. But in the end the RAS accepted de Sitter's contribution.

Another story which is intriguing has to do with the removal of the Radcliffe Observatory from Oxford to South Africa. It had been set up by John Radcliffe in the eighteenth century, and hardly any student had used it for the past hundred years. (It was Dr Knox Shaw, the Radcliffe observer, who originally proposed that his observatory be moved away from Oxford. In one of his letters to de Sitter he remarks that the students

had made practically no use of his observatory for a very long time. Yet one of Einstein's chief arguments against the removal was that one could not justify the loss of amenities, which the University of Oxford would suffer as a consequence.) Oxford is not blessed with the kind of weather that facilitates observing. A number of influential astronomers felt that it would be useful to move the observatory to Johannesburg, but there was some opposition, led by Lindemann, who was at that time an influential scientist in Oxford. He had enlisted the support of Einstein, while de Sitter was a supporter of the astronomers. Because the observatory was administered by a Trust Fund, the matter had to be decided in the High Court.

de Sitter wrote to Einstein to say that he had seen a letter over Einstein's signature, and that he [de Sitter] could not believe that Einstein knew what he was signing. Einstein wrote back rather crossly that of course he knew what he was signing. de Sitter then sent an affidavit to the proposers of the move in which he said that, though Einstein was a very great scientist, his knowledge of astronomy was minimal and his advice in this matter should be ignored. Counsel for the proposers felt that such a letter would not be helpful to their cause, and de Sitter was asked to remove the reference to Einstein from his affidavit.

The last letter from Einstein was written in 1933. He thanked de Sitter for his offer of help, but said that he was managing "to survive with his own (family)", and was even able to help others "over the water". He did not expect to be able to save very much from Germany, as proceedings had been started against him for high treason.

Soon after this Einstein moved to Princeton, where he lived and worked until his death in 1955. de Sitter's health failed, and he died in 1934.

An accelerating Universe

James E. Gunn*

Hale Observatories, California Institute of Technology, Carnegie Institution of Washington, Pasadena, California 91125

Beatrice M. Tinsley*†

Lick Observatory, University of California at Santa Cruz, California 95060

New data on the Hubble diagram, combined with constraints on the density of the Universe and the ages of galaxies, suggest that the most plausible cosmological models have a positive cosmological constant, are closed, too dense to make deuterium in the big bang, and will expand for ever. Possible errors in the supporting arguments are discussed.

"If then, Socrates, in many respects concerning many things—the gods and the generation of the Universe—we prove unable to render an account at all points entirely consistent with itself and exact, you must not be surprised. If we can furnish accounts no less likely than any other, we must be content."

Plato, *Timaeus*

*Alfred P. Sloan Foundation Fellow.

†Present address: Yale University, New Haven, Connecticut 06520.

THE cosmological constant has been invoked on several occasions to correct some seemingly real difficulty with the cosmological predictions of standard general relativity^{1,2}. The most notable of these were its initial use by Einstein to produce static universes, the models by Lemaitre designed to explain how the Solar System could be older than the then accepted value of the Hubble time, and most recently by Petrosian *et al.*³ in an attempt to explain the concentration in QSO number counts near $z = 2.0$. In each of these cases either the rationalisation for the introduction of non-zero Λ has disappeared with better data or understanding, or the application has been unsuccessful in its intended purpose.

We seem to be in the situation once again where the data may call for Λ to be dusted off and inserted in the field equations. The rationale now is the almost-zero formal value for the deceleration parameter obtained by Gunn and Oke⁴ which, when reduced by any reasonable evolutionary correction, yields negative values for q_0 much larger than the formal errors.

Such negative values correspond to accelerated expansion and require a net repulsive force. Within the framework of general relativity, a positive Λ is the only way to obtain such a force. (It is perhaps worth noting that relativistic theories of gravity exist which are consistent with Solar System experiments which do not satisfy Birkhoff's theorem and in which accelerated cosmological models arise naturally (C. Caves, unpublished).)

The physical situation regarding Λ is unclear. Most relativists find it repulsive in principle rather than by observation. If it is regarded as a fundamental constant of the classical theory, it does indeed reduce the lustre of an otherwise beautiful framework. Zel'dovich⁵, however, has shown that a Lorentz-invariant stress tensor may arise quite naturally out of quantum fluctuations *in vacuo*, and if so, its form must be $\Lambda g_{\mu\nu}$. If the cosmological term is to be regarded as a piece of the stress tensor rather than a part of the theory, it would seem to be more acceptable.

In any case, comparison of the classical Hubble diagram with density estimates based on 'local' determinations seems the best way of determining the existence of a non-zero Λ . We shall see, in fact, that the Hubble diagram alone may dictate that Λ be non-zero.

The data do not demand this conclusion, and there is the possibility that systematic errors remain, but the suggestion is strong enough that we thought it worthwhile to investigate the models in the light of other relevant observations, in the spirit of the recent work of Gott *et al.*⁶ for models with $\Lambda = 0$.

Properties of Friedman models with $\Lambda \neq 0$

Three parameters specify a model completely. A set usefully related to observables is the density parameter

$$\Omega = 8\pi G\rho_0/3H_0^2$$

(where G is the gravitational constant, ρ_0 is the present density and H_0 is the Hubble constant), the deceleration parameter q_0 ($= -\ddot{R}_0 R_0/\dot{R}_0^2$, where R_0 is the present expansion scale factor), and H_0 . An alternative set that is related to the nature of the function $R(t)$ is the ratio Λ/Λ_c (where Λ_c is the critical value, $\Lambda_c^{-1/2} = 4\pi G\rho R^3/c^2$), which remains constant during evolution of the Universe—and a dimensionless scale factor to specify the present epoch, such as $kR^2\Lambda_c$ and a scale such as H_0 . (Relationships among these quantities are given in refs 3 and 7.) We note now that $\Lambda/3H_0^2 = (\Omega/2) - q_0$, so if $q_0 < 0$, Λ must be > 0 .

Figure 1 depicts the model types in the $(q_0, \log \Omega)$ plane, with small inserts showing schematically the function $R(t)$. Lemaître models, with an extended quasistatic period, occur for Λ only slightly greater than Λ_c . Note that space is hyperbolic, flat, or spherical according to whether the quantity $(3\Omega/2) - q_0 - 1$ is negative, zero, or positive: but if $\Lambda > 0$, closure no longer means necessarily that the Universe will stop expanding, whereas for all models with $q_0 < 0$, the expansion continues indefinitely.

Constraints

To establish constraints on possible model parameters, we need a third dimension (H_0) in Fig. 1. In Fig. 2 this is represented partially by separate $(q_0, \log \Omega)$ diagrams for two values of H_0 , using an expanded scale in the area that will include any viable models (the parameter space studied by Gott *et al.* is represented by the lines $\Lambda = 0$).

Maximum redshift. If $q_0 < -1$, then models with a maximum redshift, z_m (that is a minimum R) occur if $\Omega < \Omega_c(q_0)$, the value of Ω on the line $\Lambda = \Lambda_c$. The value of z_m at a given q_0 is then less than a critical value $z_c(q_0)$, shown in several places in Fig. 1. The existence of a QSO at $z = 3.53$ immediately shows that if $q_0 < -1.13$, models below the critical line are ruled out. More seriously, thermalisation of the background radiation requires a redshift of at least 100. Models with such a

large maximum redshift have $\Omega < 2 \times 10^{-6}$, which is impossible, so we can eliminate at once the whole parameter range $q_0 < -1$, $\Lambda < \Lambda_c$. This constraint is not shown in Fig. 2, since it will be implied by a more stringent limit later.

Ages of galaxies. A lower limit to the age of the Universe (t_0) is given by limits for the ages of stars and elements in the Galaxy, $\approx 8 \times 10^9$ yr (ref. 6). This rules out models with $H_0 t_0 < 0.40$ and 0.64 for $H_0 = 50$ and $80 \text{ km s}^{-1} \text{ Mpc}^{-1}$ respectively, which lie above and to the right of the areas shown in Fig. 2 (compare the $H_0 t_0$ contours in Fig. 1), so will be eliminated by stronger constraints.

To set an upper limit is more complicated. A reasonable upper limit to the ages of globular clusters is 16×10^9 yr (compare the references cited in ref. 6); nucleochronometers cannot provide a model-independent upper age limit for the Galaxy⁸.

Evolutionary models for giant elliptical galaxies predict that their colours would be redder than is observed for ages greater than 16×10^9 yr, if their composition is solar (B. M. Tinsley and J. E. Gunn, see ref. 20). Their spectra indicate an overabundance of metals, if anything, relative to the Sun⁹⁻¹³, so we take as a safe upper limit 18×10^9 yr, corresponding to an underabundance by a factor of 2. Though it seems natural in most theoretical scenarios to form galaxies at a time roughly equal to the dynamical time of the galaxy (a few times 10^8 yr), galaxies can form later, given enough dissipation to enable them to evolve to their present condensed states. The perturbation equations (see, for example, ref. 14) require that galaxy formation occurs before the time when Ω becomes small. This is a significant constraint for small H_0 ; the locus of those models for which $\Omega = \frac{1}{2}$ 18×10^9 yr ago is shown in Fig. 2a. Models near this limit in the $k = +1$ region have relatively small redshifts at the latest allowable epoch of galaxy formation and are thus afflicted with very large evolutionary corrections (see below) and are inconsistent with the limits on the blue-visual cosmic light^{15,16} unless the radiation from

Fig. 1 Friedman models in the $(q_0, \log \Omega)$ plane. Solid curves show the models with $\Lambda = 0$, $\Lambda = \Lambda_c$, $k = 0$ as indicated. Dashed lines give dimensionless ages, $H_0 t_0$ (which are infinite at and below the critical curve for $q_0 < -1$). Small inserts show the expansion function $R(t)$ schematically. Numbers in brackets on the critical curve show the limiting redshift for asymptotic (Eddington) models on this curve, which is greater than the maximum redshift in models below or to the left of that point.

young galaxies is strongly absorbed. Galaxies can form shortly after decoupling at large redshifts only if $t_0 \lesssim 18 \times 10^9$ yr; this line is shown in Fig. 2a and b. For $H_0 = 30 \text{ km s}^{-1}$, all models with $\Lambda \geq 0$, $q_0 < 1$ are older than this.

Density. A lower limit to Ω is the contribution, Ω^* , of matter associated with galaxies. Gott *et al.* estimate $0.04 \lesssim \Omega^* \lesssim 0.08$, and we consider that an interval no greater than $0.02 \lesssim \Omega^* \lesssim 0.3$ is consistent with all the evidence discussed. The dynamical effects of Λ will invalidate an estimate of Ω^* in a region with $\rho < |\Lambda|/4\pi G$, that is, with density contrast $\rho/\rho_0 < 2|\Lambda|/$

Fig. 2 Constraints in the $(q_0, \log \Omega)$ diagram for: a, $H_0 = 50$ and b, $H_0 = 80 \text{ km s}^{-1} \text{ Mpc}^{-1}$. Heavy lines correspond to $\Lambda = 0$, $k = 0$ as in Fig. 1. The two boundaries labelled Ω^* are limits on the dynamically detectable density, and the density limit D/H is an upper bound if deuterium is cosmological. The solid black area is for models with $0 < (\Lambda/\Lambda_c) - 1 \ll 1$ which are ruled out by the absence of focusing effects; all models with $\Lambda < \Lambda_c$ (no big bang) are ruled out. Constraints based on the ages of galaxies (t_{gal}) are discussed in the text, as are those based on the Hubble diagram and labelled best fit, -1σ , and -2σ .

$3\Omega H_0^2 = |\Omega - 2q_0|/\Omega$. All of the models that will be allowed in Fig. 2 have $(|\Omega - 2q_0|)/\Omega \lesssim 100$ so they are consistent *a posteriori* with the use of Ω^* from the dynamics of bound clusters. It may not, however, be valid to derive an upper bound on Ω^* from the uniformity of the Hubble flow in some models.

Figure 2 shows the lower bound $\Omega > \Omega^* > 0.02$, which is independent of H_0 .

An upper limit to Ω is not so safe because matter could be hiding outside galaxies or clusters⁶. The requirements on smoothness are less severe if $|\Lambda|/4\pi G$ is significant compared with the mean density, but the least contrived situation is that $\Omega \sim \Omega^* < 0.3$. This value is shown as an upper bound in Fig. 2.

A more stringent upper limit is obtained if we believe that deuterium is produced in the big bang. Studies of nucleosynthesis in supernova shocks, subsequent to those cited by Gott *et al.*, have not provided a clearcut answer as to whether supernovae could be the source of galactic deuterium^{17,18}.

If production in a 'canonical' big bang is required, then the best estimate⁶ is $\rho_0 < 4 \times 10^{-31} \text{ g cm}^{-3}$, which is indicated as a possible upper limit to Ω in Fig. 2.

Quasars. In Lemaitre models, a peak in the redshift distribution of extragalactic objects is predicted at the inflection redshift z_i , at which q changes sign from positive to negative; its value is given by $(1+z_i)^3 = (\Omega - 2q_0)/\Omega$. From the absence of a significant peak in QSO counts at $z < 2$, and from the calculations of Petrosian and coworkers^{1,3,19} we believe that models with $1 < \Lambda/\Lambda_c < 1.1$ ($k = +1$) and $z_i < 2$ can be ruled out. In fact, we believe that all ($k = +1$) models for which the radial coordinate reaches π at a redshift $z\pi < 3$ can be ruled out. These models have a range of redshift around $z\pi$ for which objects are very bright, and it is unlikely that bright galaxies and quasars from such redshift ranges would have escaped detection. This limit is a bit more stringent than the one applied to the counts, and the forbidden region is indicated by the solid black area at the left of Fig. 2a and b.

Hubble diagram. The interpretation of the Hubble diagram is quite complex, and its understanding is contingent on understanding the evolution of elliptical galaxies. Ignoring evolution, Gunn and Oke⁴ get an apparent value $q_{0a} = -0.15 \pm 0.57$ (1σ) for their favoured statistical sample, from a set of galaxies most of whose weight for this problem comes from redshifts in the vicinity of 0.3.

This is consistent with the classical steady-state value $q_0 = -1$, within the errors, in which case no evolutionary correction can be applied. The steady-state model seems, however, to be very unlikely on other grounds, such as production of the microwave background radiation.

The evolutionary correction from population syntheses of ellipticals is (ref. 4 and B.M.T. and J.E.G., unpublished).

$$\Delta m(z) \simeq -(1.3 - 0.3x) \ln \left\{ \frac{t_0 - t(z)}{t_{\text{gal}}} \right\}$$

where t_0 is the present age of the Universe, $t(z)$ is the age at z and t_{gal} is the present age of the Galaxy; x is the slope of the initial mass function. The first order correction to q_0 from this magnitude change is

$$EC = q_{0a} - q_0 = \frac{2.5}{\ln 10} \frac{2}{2-\alpha} \frac{1.3-0.3x}{H_0 t_{\text{gal}}}$$

where $\alpha \sim 0.7$ is the slope of the flux-diameter relationship for ellipticals⁴. For reasonable values of the parameters, EC is always positive.

Results on red and infrared line indices demand that $x \leq 1$ if the initial mass function can be represented by a power law (B. M. Tinsley and J. E. Gunn, unpublished). We have thus taken $x = 1$, since this must underestimate $|EC|$, and we have

likewise taken the largest possible number for t_{gal} ; that is, t_0 or 18×10^9 yr, whichever is smaller. We then constructed Hubble diagrams for a set of models in the Ω, q_0 region of interest ($\Lambda \geq 0$, $0.01 < \Omega < 1$, $\Lambda > \Lambda_{\text{crit}}$ for $k = +1$). The Malmquist correction was applied as outlined previously⁴ for a dispersion in absolute magnitude $\sigma = 0.4$. The standard deviation in q_{0a} was then converted into a magnitude difference at $z = 0.3$. This simplification enables the goodness of fit of any model to be checked approximately by calculating its predicted magnitude at $z = 0.3$ and comparing this with the value given by q_{0a} with no EC and the 1σ and 2σ limits given by the formal errors on q_{0a} . The approximation should be very good, since the relevant data are strongly concentrated at about this redshift, and the comparison is, to first order, independent of redshift. The results, in the form of best fit lines and contours at 1σ and 2σ are plotted on Fig. 2a and b. All models are ruled out at the 2σ level if H_0 is as small as 30.

For $H_0 = 50$ (Fig. 2a), there is almost no model which agrees within 1σ , none which satisfies the Ω^* constraint, and certainly none which makes deuterium. At the 2σ level, a wide variety of models is possible, including models of both curvatures. None of these models which satisfy the Ω^* constraint can make galaxies early; and all must have positive Λ .

For $H_0 = 80$, the ages are much smaller, and the age constraint on the galaxies easier to satisfy. A larger collection of models can make galaxies early, and thus the evolutionary corrections can be smaller. There is a small portion of the best fit line in the allowable region on this diagram, but none of these models can make deuterium, and all are close enough to $\Lambda = \Lambda_{\text{crit}}$ that they have peculiar Hubble diagrams at large redshifts ($z \sim 2-3$), and may be ruled out on that basis in the future. All are closed. Models at the -1σ and -2σ levels can make galaxies early, can make deuterium, and can be either open or closed. Again all require that $\Lambda > 0$, but the -2σ contour approaches the $\Lambda = 0$ locus very closely for small Ω . It is perhaps worth noting that if the Ω^* level is put in at the 'best' value of 0.06 found by Gott *et al.*, no models with H_0 this large can make deuterium. All of these remarks about deuterium of course refer to the 'standard big bang' nucleosynthesis models and can be relaxed somewhat if one considers various complications (see ref. 6).

Summary of constraints. Thus it would seem that the data suggest (1) that the universe is closed, (2) that the density is fairly high ($\Omega \gtrsim 0.1$), (3) that $\Lambda > 0$, and in fact, that Λ is within a factor 2 of Λ_{crit} , (4) that H_0 is at least about $80 \text{ km s}^{-1} \text{ Mpc}^{-1}$, and (5) that deuterium is not primordial. We are, of course, not compelled to believe all of these conclusions, since within 2σ of the best fit are a large number of other possibilities, but no models with $\Lambda = 0$; this state of affairs is independent of H_0 , but can become more stringent if H_0 is small enough that galaxies are made late. All of the even remotely allowable models expand forever. The $q_0 = 1/2$, $\Omega_0 = 1$ model which is the 'closest' boundary point of the set of $\Lambda = 0$ models in the $q-\Omega$ diagram in which the models undergo collapse in the future is 4σ away from the observations.

Conclusion

The first reaction to all this is that something must be terribly wrong, and we conclude therefore with some of the possible pitfalls.

Systematic effects in the photometry. Since the low and high redshift samples in Gunn and Oke's analysis⁴ had to be treated differently due to technical difficulties, there is a possibility that the two sets are not corrected properly to the same system. It seems highly unlikely that the error is as large as 0.05 mag, however, which corresponds to an error in q_0 of less than 0.25. An increase in the measured q_0 by this amount would make the fitting problem less extreme but would not substantially change the situation presented here.

Intergalactic obscuration. An absorption of 0.2 mag at $z = 0.3$ will decrease the measured q_0 by 1. This requires a gas density

corresponding to $\Omega \sim 0.03$ if there is the same dust-gas ratio as the interstellar medium in the solar neighbourhood. The presence of so much dust seems *a priori* exceedingly unlikely, but it may be possible to create scenarios in which this much nuclear processing occurs and is followed by ejection of grains into intergalactic space.

Galactic evolution. The evolutionary corrections are of course crucial to the interpretation given here, and one may reasonably ask how uncertain they are. In our opinion there are two major sources of uncertainty. First, the power-law approximation to the main-sequence mass function may be seriously misleading. Until careful and accurate evolutionary effects on galactic spectra can be observed, this will be difficult to check. Second, there may be serious troubles with stellar evolution theory (we clearly do not understand the Sun) but empirical checks with galactic clusters and the old disk (B. M. Tinsley and J. E. Gunn, unpublished) make large errors here a bit unlikely. The constraints we adopted on the age of galaxies, however, are critically dependent on the synthetic colours and could possibly be in error. Since our conclusions about the Hubble constant are affected strongly by this constraint, they should be regarded with due caution.

Dynamical evolution. It is possible that the central galaxies in clusters could undergo accretion of other cluster members through dynamical friction effects on a time scale which is sufficiently short to affect significantly the evolution of the total light. Preliminary estimates indicate that the effect is probably not important, but there are a great many uncertainties, including the question of how much of the cluster mass resides in the galaxies themselves, and whether clusters typically have a cold central subsystem from which accretion could occur rather efficiently. It seems futile to try to estimate the effect more accurately until at least these questions are answered.

Density limits. The constraint on Ω^* is weakened somewhat by the possible existence of a non-zero Λ , since the local super-cluster flow uniformity is no longer an effective argument, but the other arguments seem still quite persuasive. It is of course not clear what the status of the primaeval deuterium production constraint is, nor will it be until one can reasonably rule out subsequent production.

It is clear that if H_0 is small, the age constraint on galaxies is correct, and q_0 is large and negative, then deuterium probably cannot be primordial, Ω cannot be small, and one cannot escape the conclusion that Λ is non-zero and positive. The incorrect piece(s) of the puzzle are well hidden, and the situation is, as is usual in observational cosmology, that one awaits new and better data.

This work was supported in part by grants from the National Science Foundation.

Note added in proof: More detailed calculations by J. P. Ostriker and S. D. Tremaine (*Astrophys. Lett.*, in the press) and S. D. M. White (unpublished) show that the effect mentioned in the paragraph "Dynamical evolution" may be more important.

Identification of two copies of the gene for the elongation factor EF-Tu in *E. Coli*

S. Richard Jaskunas, Lasse Lindahl & Masayasu Nomura

Institute for Enzyme Research, Departments of Biochemistry and Genetics,

Richard R. Burgess

McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, Wisconsin 53706

Two copies of the structural gene for the elongation factor EF-Tu have been identified in Escherichia coli: one near rif and the other near str. The latter seems to belong to a single transcriptional unit together with the genes for ribosomal protein S7, S12 (str) and the elongation factor EF-G (fus).

PROTEIN chain elongation factors, EF-G, EF-Tu and EF-Ts, have been characterised as components required for protein synthesis in *Escherichia coli* (for reviews, see refs 1-3). In addition to their role in protein synthesis, both EF-Tu and EF-Ts are known to be components of Q β -replicase⁴. Furthermore, EF-Tu has been suggested to function as a positive regulatory factor for the transcription of rRNA genes^{5,6}. Since these protein chain elongation factors, especially EF-G and EF-Tu, function in close association with the ribosome, one could reasonably expect that their amounts inside a cell would be regulated coordinately with the amount of ribosomes. Such coordinated regulation has been observed for EF-G and EF-Ts (refs 7 and 8). No study has, however, been reported on the regulation of EF-Tu (see ref. 8).

To study the regulation of synthesis of the elongation factors, information on the organisation of the genes for these factors is essential. The gene for EF-G has been identified and mapped^{9,10} at 64 min near the *str* locus that codes for ribosomal protein (r-protein) S12, but no information was available concerning the genes for EF-Tu and EF-Ts. In this paper, we report the identification of the gene for EF-Tu. It was found that there are at least two copies of the gene for EF-Tu on the haploid chromosome of *E. coli*; one is located close to the *str* gene at 64 min and the other is at 79 min close to the *rif* gene which codes for the β -subunit of RNA polymerase¹¹. In addition, the former gene seems to belong to a single transcriptional unit together with the genes for EF-G (*fus*), r-protein S12 (*str*), and S7.

λ *fus2* and λ *rif*^{d18} carry EF-Tu genes

Several λ transducing phages carrying many r-protein genes from the *str-spc* region of the *E. coli* chromosome at 64 min have been isolated previously¹¹. One of them, λ *fus2*, carries about 30 r-protein genes, and in addition, the *fus* gene which codes for EF-G. In addition to the *str-spc* region, several 50S r-protein genes are also located near *rif* at 79 min. It has been found^{12,40} that λ *rif*^{d18}, originally isolated by Kirschbaum and Konrad¹³, carries several 50S r-protein genes in addition to the genes for RNA polymerase subunits β and β' (ref. 14). Because of the close relationship between elongation factors and ribosomes, we have investigated the possibility that genes for EF-Tu and EF-Ts might be located close to the r-protein genes carried by λ *fus2* (or λ *rif*^{d18}) as is the case with the *fus* gene.

First, ultraviolet-irradiated *E. coli* cells were infected with purified transducing phages, and proteins synthesised after phage infection were labelled with ³⁵S-methionine and analysed

(see ref. 11, and the legend to Fig. 1). Ultraviolet irradiation damages bacterial DNA and decreases the synthesis of RNA and protein to a negligible level without serious damage to the RNA and protein synthesis machinery. Thus, large stimulation in the synthesis of any protein observed after introduction of intact transducing phage DNA is a strong indication of the presence of a structural gene for that protein on the transducing phage DNA. A λ lysogen was used to prevent the expression of λ genes on the infecting transducing phages. The proteins synthesised after infection with the transducing phages were analysed by sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis¹⁵ followed by autoradiography (Fig. 1).

It can be seen that λ *fus2* stimulated the synthesis of several proteins. Comparison to the reference proteins indicated the presence of a radioactive protein band corresponding to the EF-G band as expected. The presence of EF-G in this band was confirmed by tryptic peptide analysis (data not shown). In addition, we found radioactive protein bands with the mobilities of the reference EF-Tu (see below) and the reference RNA polymerase subunit α (S.R.J., R.R.B., and M.N., unpublished). In contrast to λ *fus2*, neither λ *spc2* nor λ *spc1* stimulated the synthesis of the proteins corresponding to EF-G and EF-Tu. λ *spc2* and λ *spc1* are other transducing phages carrying r-protein genes including *spc*, but not *fus* (see ref. 11 and Fig. 5). To our surprise, however, we found that λ *rif*^{d18} also stimulated the synthesis of a radioactive protein which migrated like EF-Tu on the SDS-gel system used.

The radioactive proteins with the mobility of EF-Tu were further characterised. These proteins were synthesised after λ *fus2* or λ *rif*^{d18} infection in the presence of ³⁵S-methionine. We call them λ *fus2*-EF-Tu and λ *rif*^{d18}-EF-Tu, respectively. The following observations were made. (1) As described above, both λ *fus2*-EF-Tu and λ *rif*^{d18}-EF-Tu showed the same mobility in the SDS-polyacrylamide gel electrophoresis as the reference EF-Tu (see Fig. 1b). (2) Both proteins also showed the same mobility in another polyacrylamide gel electrophoresis system (pH 8.7, in 8 M urea) as the reference EF-Tu (data not shown). (3) Both λ *fus2*-EF-Tu and λ *rif*^{d18}-EF-Tu labelled with ³⁵S-methionine were purified by SDS-polyacrylamide gel electrophoresis and then digested with trypsin. The resultant methionine-containing peptides were compared with those obtained from a reference EF-Tu purified from cells labelled with ³⁵S-methionine. Radioactive methionine containing tryptic peptides were analysed by paper electrophoresis at pH 3.6. As Fig. 2 shows, both radioactive proteins, λ *fus2*-EF-Tu and λ *rif*^{d18}-EF-Tu, in fact showed a tryptic peptide pattern identical to that of reference EF-Tu. (4) Both radioactive proteins reacted with a specific antiserum against purified EF-Tu, but not with an antiserum against EF-G (data not shown). From these results, we conclude that both λ *fus2* and λ *rif*^{d18} stimulated the synthesis of EF-Tu in the ultraviolet-irradiated *E. coli* cells.

We have also demonstrated that the DNAs from λ *fus2* and λ *rif*^{d18} are both active in the synthesis of EF-Tu in an *in vitro* DNA-dependent protein synthesising system described previously¹⁶. As described in Fig. 3, radioactive proteins synthesised

Fig. 1 Electrophoresis of proteins synthesised in ultraviolet-irradiated bacteria after infection with transducing phage. *a*, Reference proteins were electrophoresed on 8.75% polyacrylamide disc gels containing 0.1% sodium dodecyl sulphate (SDS) as described previously¹⁵. The samples were: (1) RNA polymerase; (2) EF-Ts; (3) EF-Tu; (4) EF-G; (5) a mixture of RNA polymerase, EF-Ts, EF-Tu, EF-G and several molecular weight markers. Gels were stained with Coomassie brilliant blue. The bands are identified on the left. *b*, Infection of ultraviolet-irradiated *E. coli* cells with transducing phages was performed essentially as described previously¹¹. The host was a λ lysogen of *E. coli* K12 strain 159 (ref. 32). The culture medium was a synthetic minimal medium³³ containing maltose (0.4%) and B1 (1 μ g ml⁻¹). The multiplicity of infection was approximately 10. For each sample, 5 μ Ci of ³⁵S-methionine (323 Ci mmol⁻¹) was added to a 2.5 ml culture 30 min after infection. After a 10 min labelling period and a 1-min chase with non-radioactive methionine (1 mg ml⁻¹), the culture was diluted with 5 ml of ice-cold minimal medium without maltose. The cells were pelleted, washed once with 0.05 M Tris-HCl (pH 7.9), and stored at -20 °C. Cell pellets were resuspended in 250 μ l SDS-gel sample buffer [3% (w/v) SDS, 5% (v/v) 2-mercaptoethanol, 10% (v/v) glycerol, 0.063 M Tris-HCl pH 6.8], heated for 2 min at 90 °C, and 25 μ l electrophoresed in parallel with the reference proteins shown in (*a*). The stained and destained gels were sliced longitudinally, dried down under vacuum on to a piece of filter paper, and subjected to autoradiography using Kodak No-Screen X-ray film. The autoradiogram shown was exposed for 4 d. The samples were ultraviolet-irradiated cells infected with: (1) λ fus2; (2) λ rif^d18. Gel 2 contained a 1:1 mixture of the samples applied to gels 1 and 4. The sample for gel 3 was uninfected non-irradiated cells labelled with ³⁵S-methionine. The ultraviolet-irradiated cells infected with λ c1857S7 did not show any radioactive band (compare sample 1 in Fig. 4).

in vitro using λ fus2 DNA and λ rif^d18 DNA as template were first analysed by SDS-polyacrylamide gel electrophoresis. The radioactive proteins with the mobility of EF-Tu were detected in both cases. These proteins were eluted from the gels and examined for their reaction to specific antisera against EF-Tu, EF-G and r-protein L1, respectively. As shown in Fig. 3, radioactive proteins synthesised with λ fus2 DNA and λ rif^d18 DNA as template both reacted with the anti-EF-Tu serum but not with the other two antisera used. These experiments demonstrate that a protein very similar or identical to the reference EF-Tu was synthesised using either λ fus2 DNA or λ rif^d18 DNA as template. From all these experimental results, we conclude that both λ fus2 and λ rif^d18 carry a structural gene for EF-Tu.

In preliminary experiments, we have attempted to find a gene for EF-Ts on either the λ fus2 or λ rif^d18 chromosome, but with negative results.

Transcriptional unit containing *str*, *fus* and an EF-Tu gene

We have isolated several mutants of λ fus3 that have a decreased expression of the EF-Tu gene in ultraviolet-irradiated cells. λ fus3 is a derivative of λ fus2 which carries a *str*⁺ allele instead of the *str*⁻ allele present on λ fus2. We started from a lysogen (NO1380) carrying λ fus3 and with chromosomal markers *recA*⁻, *trkA*⁻, *spc*⁺, *str*⁺ and *fus*⁺. Since the *spc*⁺, *str*⁺ and *fus*⁺ alleles carried by λ fus3 are dominant over the corresponding resistant alleles on the chromosome, the phenotype of the lysogen is sensitive to all three antibiotics, that is, streptomycin, spectinomycin and fusidic acid (Str-S, Spc-S and Fus-S). We selected spontaneous Str-R mutants on media with a low potassium concentration and containing Str. By using media with a low potassium concentration, we avoided selecting mutants that had simply lost the transducing phage since the *trkA*⁺ gene on λ fus3 is required for growth on low potassium media¹⁷. Any mutation which inactivates the expression of the

Fig. 2 Electrophoresis of ³⁵S-methionine tryptic peptides of EF-Tu. The three samples containing ³⁵S-methionine labelled EF-Tu described below were electrophoresed with 1 μ g pure EF-Tu as described in Fig. 1. The stained band corresponding to EF-Tu sized protein was cut out from each gel, washed in water, crushed, equilibrated with 0.1 M NH₄HCO₃, and incubated for 24 h at 37 °C with 100 μ g ml⁻¹ TPCK treated trypsin. Solutions were separated and the gel particles were again treated with trypsin. The solutions from the two trypsin treatments were pooled. The peptides eluted into the solution were recovered by lyophilisation and electrophoresed on Whatman 3 MM, 25 V cm⁻¹, for 2.5 h with H₂O, glacial acetic acid, pyridine (90:10:1) at pH 3.6. The origin is at 0. Strips (1-cm) were counted by liquid scintillation counting. The samples were: *a*, The EF-Tu sized protein synthesised in ultraviolet-irradiated cells after infection with λ rif^d18; *b*, the EF-Tu sized protein synthesised in ultraviolet-irradiated cells after infection with λ fus2; *c*, reference EF-Tu. The source of the reference EF-Tu was as follows. First, a partially purified EF-T preparation was made from uninfected non-irradiated *E. coli* cells [strain 159(λ)] grown in the presence of ³⁵S-methionine. The purification was done according to the previously described procedures^{34,35} as modified by W. A. Strycharz (personal communication). The cells were broken with alumina and a S100 supernatant was treated with protamine sulphate and fractionated with ammonium sulphate and isopropanol³⁴. The protein fraction containing EF-T was applied to a DEAE-Sephadex column³⁵. The column was first washed with 0.15 M KCl; EF-T was then eluted with 0.30 M KCl. The partially purified EF-T preparation thus obtained was subjected to electrophoresis on an SDS-polyacrylamide gel. The electrophoresis separated EF-Tu from Ts and all other contaminating proteins in the EF-T preparation. Pure EF-Tu prepared in this way was used as the reference EF-Tu.

Fig. 3 Identification by radioimmunodiffusion of EF-Tu synthesised *in vitro*. ^{35}S -methionine-labelled protein was synthesised in a DNA-dependent cell-free system, using DNA from λfus2 ($35 \mu\text{g ml}^{-1}$) and that from λrif^{18} ($40 \mu\text{g ml}^{-1}$) as template. The method was similar to those described previously^{11,16}. After incubation at 37°C for 90 min, samples were treated with RNase ($10 \mu\text{g ml}^{-1}$) and DNase ($10 \mu\text{g ml}^{-1}$) at 37°C for 10 min. The resultant samples ($60 \mu\text{l}$ each) were mixed with $200 \mu\text{l}$ of the SDS-gel sample buffer (see Fig. 1), heated at 95°C for 5 min, cooled and dialysed against 4 changes of 50 ml of the SDS-gel sample buffer¹⁸. The samples were then subjected to the SDS-polyacrylamide gel electrophoresis as described in Fig. 1 and the radioactive products were detected by autoradiography. The radioactive proteins which had mobilities identical to reference EF-Tu were eluted from the sliced gels. This was done by crushing the gels and incubating them with 1.5 ml of $0.1 \text{ M NH}_4\text{HCO}_3$ ($\text{pH} \sim 8.0$) for 20 h at 37°C . Bovine serum albumin ($50 \mu\text{g}$) was added to the eluates and the mixtures were lyophilised. Lyophilised proteins were then dissolved in $50 \mu\text{l}$ of Tris-HCl (0.03 M , $\text{pH} 7.4$)-MgCl₂ (0.02 M)-KCl (1 M)-2-mercaptoethanol (0.006 M) buffer containing the following carrier proteins: purified T (EF-Tu and EF-Ts), $3 \mu\text{g}$; purified EF-G, $2 \mu\text{g}$; unfractionated 50S ribosomal proteins, $30 \mu\text{g}$. These protein mixtures containing radioactive proteins were analysed by immunodiffusion as described before^{16,36}. The samples were placed in the centre wells and antisera against EF-Tu ("A-Tu"), EF-G ("A-G") (both gifts from H. Weissbach) and 50S protein L1 ("A-LI")¹² were placed as indicated in the figure (both in a and b). Each set of pictures shows a gel (a and b) and an autoradiogram of the dried gel (c and d). The results obtained with the sample containing the *in vitro* product using λfus2 DNA as template are shown in a and c and those obtained using λrif^{18} DNA are shown in b and d. It can be seen in both cases that only the Tu-anti-Tu precipitin bands contained radioactive proteins and the other precipitin bands did not.

str^s gene on λfus3 or changes it to a *str^r* allele will lead to the Str-R phenotype. Among 25 independent Str-R mutant lysogens isolated, 15 were Fus-R (but not Spc-R). Transducing phages were isolated and characterised. Phages that seemed to have a mutation inactivating the *str^s* and *fus^s* genes were further analysed for their ability to stimulate the synthesis of EF-G, EF-Tu and r-proteins. Table 1 and Fig. 4 give the results obtained with two mutant transducing phages, $\lambda\text{fus3-}\Delta 101$ and $\lambda\text{fus3-I103}$. As can be seen, these two mutations substantially reduce the expression of the genes for EF-G, EF-Tu, S12 (*str*), and S7. It should be noted that the expression of these genes does not seem to be completely eliminated. For example, a small amount (about 3% of the parent) of EF-G seems to be made from $\lambda\text{fus3-}\Delta 101$ (see Fig. 4). This suggests that the inactivation of some or all of these genes is not a direct inactivation such as that caused by a deletion.

The mutations carried by these two transducing phages, $\Delta 101$ and I103, were characterised by the density of the mutant phages and by electron microscopic analysis of heteroduplexes of the mutant phage DNAs and several other phage DNAs including the λfus2 DNA. We have found that mutation I103 is an insertion of a small DNA with the size of IS2 (refs 18–20) and is located close to the right end of the bacterial genome carried by λfus3 (see Fig. 5). The distance between the site of the insertion and the right *coli-λ* junction was found to be 0.60 ± 0.10 kilobase (kb) in length. Mutation $\Delta 101$ was found to be a

small deletion which is also located near the right end of the λfus3 chromosome. This deletion removes the *coli-λ* junction; it deletes about 0.3 kb of λ DNA together with about 1.3 kb of the right end of the bacterial DNA (Fig. 5). The sum of the minimum probable sizes of each of the inactivated genes, that is, the structural genes for EF-G, EF-Tu, S12 and S7, can be calculated from the molecular weights of these proteins. The sum is 4.6 kb in length, and is much larger than the bacterial DNA removed by $\Delta 101$ or the space between the right "*coli-λ*" junction and the site of the I103 insertion. Thus, most of the inactivated genes seem to be located left of the mutations $\Delta 101$ or I103. We conclude that most of the genes for EF-G, EF-Tu, S12 (*str*) and S7 are not deleted, but inactivated by some kind of polar effect. Since the direction of the transcription in this region is from right to left²¹, and there is no known λ promoter on the λ DNA present on λfus3 , the transcription of these genes seems to be from a bacterial promoter which would be located near the right end of the bacterial DNA. Thus, the polar effect of $\Delta 101$ is probably caused by the deletion of the promoter or some other essential regulatory elements for these inactivated genes. Similarly, inactivation of these genes by I103 is probably

Table 1 Relative synthesis of protein in ultraviolet-irradiated bacteria after infection with λfus3 , $\lambda\text{fus3-}\Delta 101$, $\lambda\text{fus3-I103}$

Protein	Transducing phage		
	λfus3	$\lambda\text{fus3-}\Delta 101$	$\lambda\text{fus3-I103}$
EF-G	1.0	0.03	0.19
EF-Tu	1.0	0.11	0.23
S7	1.0	0.31	0.34
S12	1.0	0.03	0.13
Others	1.0	1.02	0.99

Ultraviolet-irradiated bacteria were infected with $\lambda\text{cI857S7}$, λfus3 , $\lambda\text{fus3-}\Delta 101$ and $\lambda\text{fus3-I103}$ as described in Fig. 1. The relative amounts of EF-G and EF-Tu synthesised after phage infection were determined from the autoradiogram shown in Fig. 4. The autoradiogram was scanned with a Joyce-Loebl microdensitometer and the amounts of EF-G and EF-Tu synthesised relative to the amount of RNA polymerase subunit α synthesised were calculated from the areas of the peaks. The synthesis of α does not seem to be affected by the $\Delta 101$ and I103 mutations. Its structural gene is between *trkA* and *spc* (S.R.J., R.R.B. and M.N., unpublished). The amount of each protein synthesised was then normalised to the amount synthesised after infection with the parent phage λfus3 . The relative synthesis of S7 and S12 was determined from separate experiments in which the labelling and sample preparation were done as described previously²¹. The bacterial host for the experiment was prelabelled with ^{14}C -leucine, irradiated, and infected with transducing phages. Proteins synthesised after infection were labelled with ^3H -leucine and electrophoresed on a two-dimensional polyacrylamide gel that separates r-protein³⁰. The $^3\text{H}/^{14}\text{C}$ ratio for all the r-proteins except S1, L31 and L34 was determined. The stimulation of each r-protein *i* was calculated, $S_{rpi} = (^3\text{H}/^{14}\text{C})_{\text{transducing phage infected}} / (^3\text{H}/^{14}\text{C})_{\lambda\text{cI857S7 infected}}$. The stimulation of the synthesis of each r-protein relative to the synthesis of S4 was then determined by dividing S_{rpi} by the stimulation of the synthesis of S4, S_{rpi}/S_{rps4} . The structural gene for S4 is between *trkA* and *spc* (refs 21 and 31) and its synthesis does not seem to be affected by the $\Delta 101$ and I103 mutations. The relative stimulation of the synthesis of each protein by $\lambda\text{fus3-}\Delta 101$ and $\lambda\text{fus3-I103}$ was then normalised to the relative stimulation by λfus3 : $(S_{rpi}/S_{rps4})_{\text{transducing phage infected}} / (S_{rpi}/S_{rps4})_{\lambda\text{fus3 infected}}$. Data for S7 and S12 are presented here. The stimulation of the synthesis of some protein that comigrates with L20 is also reduced to less than 10% by $\Delta 101$ and I103. Since some S12 comigrates with L20 (ref. 30 and M.N., unpublished), it seems likely that the apparent stimulation of the synthesis of L20 by λfus3 and its reduction by $\Delta 101$ and I103 is due to the presence of S12 in this spot. The stimulation of the synthesis of each of the other r-proteins whose genes appear to be on λfus3 (27 proteins) was not significantly affected. The average of the normalised relative stimulation for these proteins is given in the bottom line. We previously observed an apparent weak stimulation of the synthesis of S7 in ultraviolet-irradiated cells after infection with λspc1 and λspc2 (ref. 11). The stimulation of the synthesis of S7 is, however, much greater with λfus3 or λfus2 (S.R.J. and M.N., unpublished). Also, we have only been able to synthesise S7 *in vitro* using λfus2 DNA as template and not with λspc1 or λspc2 DNA (L.L. and M.N., unpublished). Thus it is likely that the structural gene for S7 is present on λfus2 and λfus3 , but not on λspc1 or λspc2 .

due to a strong polar effect affecting distal genes that is analogous to the polar effect of IS2 studied in other systems¹⁸⁻²⁰. From these results, we conclude that the genes for EF-G (*fus*), EF-Tu, S12 (*str*) and S7 probably belong to a single transcriptional unit. The promoter for this transcriptional unit is presumably located in the region between the I103 insertion and the *coli*- λ junction, the region that is also covered by the Δ 101 deletion. More complicated models, however, such as the expression of one transcriptional unit being required for the expression of another unit, would also be consistent with present observations.

Because the mutations Δ 101 and I103 affect the four genes described above, but do not affect the remaining r-protein genes, including *spc* or the gene for the RNA polymerase subunit α , these latter genes presumably belong to another one or more transcriptional units. This is consistent with the previous conclusion that there is more than one r-protein gene transcriptional unit in the *str*-*spc* region of the *E. coli* chromosome²¹. As mentioned above, EF-Tu is synthesised in ultraviolet-irradiated cells after λ *fus*2, but not after λ *spc*1 or λ *spc*2, infection. These results suggest that the gene for EF-Tu is not on the λ *spc*2 genome, placing the gene location as shown in Fig. 5. This mapping position is consistent with the conclusion described above that the gene for EF-Tu is in the same transcriptional unit as *str* and *fus*.

EF-Tu gene in *rif* region

The EF-Tu gene has been mapped on the λ *rif*^d18 chromosome by making DNA fragments with various DNA restriction endonucleases and testing the ability of each fragment to synthesise EF-Tu in a DNA-dependent protein synthesising system (L.L., M. Yamamoto and M.N., unpublished). The order of the genes is shown in Fig. 5. We do not have any experimental information on the question of whether the EF-Tu gene is cotranscribed together with any of the neighbouring genes, the rRNA gene set¹², 50S r-protein genes^{12,40} or the genes for the RNA polymerase subunits β and β' (refs 14, 22 and 23).

Two genes for EF-Tu

We believe that the presence of the genes for EF-Tu on both λ *rif*^d18 and λ *fus*2 reflects the presence of at least two genes for EF-Tu on the normal *E. coli* chromosome. Since the gene for EF-Tu was not used as a selection marker to isolate the λ *rif*^d18 or λ *fus*2 transducing phages, it is difficult to imagine that the EF-Tu gene was accidentally incorporated into these transducing phages during construction of the phage. In addition, we have observed that another transducing phage, ϕ 80*rif*^r, isolated by Konrad, Austin and Kirschbaum²⁴, also stimulates synthesis of EF-Tu, in addition to RNA polymerase subunits β and β' , and several 50S r-proteins, in ultraviolet-irradiated cells (our unpublished experiments). It was also shown that the DNA of ϕ 80*rif*^r has a near complete homology to λ *rif*^d18 phage DNA in the substituted bacterial DNA region containing the 50S r-protein genes, the EF-Tu gene and the rRNA gene set, as judged by electron microscopic analysis of the heteroduplex formed from both the phage DNAs (G.D. Strycharz, and M.N., unpublished.) Since ϕ 80*rif*^r was originally isolated in a completely different way from that used for the λ *rif*^d18 isolation, this observation also supports the conclusion that the organisation of the genes found on the λ *rif*^d18 phage chromosome applies to the normal *E. coli* chromosome. We conclude that there are at least two genes for EF-Tu. We call the one near *str* and *fus* "tufA" and another near *rif* "tufB".

There are some reports on the isolation of mutants which have alterations in EF-Tu (refs 25 and 37). The genes responsible for the alterations have not, however, been mapped.

The significance of the presence of two genes for EF-Tu, one at the *str*-*spc* region and the other at the *rif* region, is a matter of speculation at the moment. The two chromosomal regions

where the *tuf* genes are located contain many of the genes for ribosome and RNA polymerase components. One could speculate that these two regions are physically proximate within *E. coli* cells and that the transcription and translation of these genes as well as the assembly of both RNA polymerase and ribosomes take place all in one place. It is possible that a physical interaction (by DNA sequence homology) between the two *tuf* genes is involved in maintaining a chromosome structure with the two regions in contact. A condensed *E. coli* chromosome structure with several "contact regions" has been proposed recently²⁶.

Alternatively, EF-Tu might function as a regulatory protein for the expression of its own operon. If such regulation takes place using a "nascent form" of EF-Tu and it acts only *cis* (that is, only on a regulatory element of its own operon), the presence of one EF-Tu gene for each important gene cluster, one at the *rif* region and the other at the *str*-*spc* region, would be required for the proper regulation.

It is also possible that the two observed *tuf* genes may be slightly different and may code for two kinds of EF-Tu that have slightly different primary structures and different cellular functions. It is equally conceivable that the presence of the two *tuf* gene copies may simply reflect a need for a greater amount of EF-Tu for cellular functions. In this connection, we note that although the stoichiometric relationship of both EF-G and EF-Ts to ribosomes has been analysed^{7,8,27}, no such work

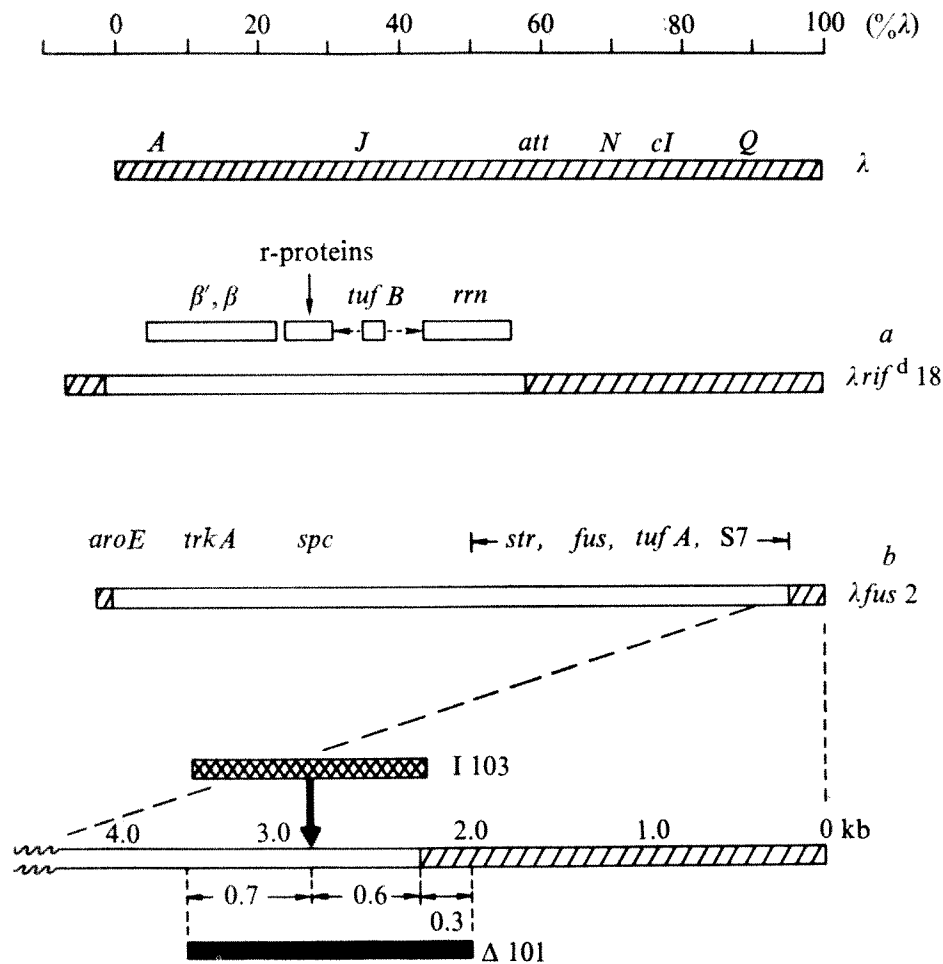

Fig. 4 Electrophoresis of proteins synthesised in ultraviolet-irradiated bacteria after infection with mutant transducing phages. Ultraviolet-irradiated cells were infected with (1) λ c1857S7, (2) λ *spc*2, (3) λ *fus*3, (4) λ *fus*3- Δ 101, and (5) λ *fus*3-I103 as described for Fig. 1. Samples were prepared and analysed by SDS-polyacrylamide gel electrophoresis as described in Fig. 1 except that the gels contained 12.5% acrylamide instead of 8.75%. Autoradiograms of dried gels are shown. Some of the bands are identified on the right.

to 48.5% λ measured from the left end of λ genome, and inserts a 50.7% λ units length fragment of bacterial DNA; λ $spc1$ deletes λ DNA from 1.9% λ to 56.8% λ and inserts 38.4% λ units length fragment of bacterial DNA; λ $fus2$ deletes λ DNA from 1.9% λ to 94.9% λ and inserts 96.5% λ units length fragment of bacterial DNA. Thus, λ $fus2$ has a homology to the DNA segment from the left end of λ $spc2$ (total about 53% λ units) and a homology to the λ DNA at the end of the molecule with the length of 5.1% λ units. The structure of these transducing phages has been determined previously (M. Fiant, W. Szybalski, F. Blattner, L.L., S. R. J. and M.N., unpublished).

has been reported with respect to EF-Tu (see ref. 8).

Finally, we have shown that the genes for EF-G (fus) and that for EF-Tu ($tufA$) probably belong to a transcriptional unit together with other r-protein genes including str . Thus we expect that both the fus gene and the $tufA$ gene are subject to the same control system as those governing r-protein genes, such as the stringent-relaxed control system^{28,29}. We do not, however, know whether the $tufB$ gene is also controlled by the same system. Thus more experiments are required to clarify the problems related to the regulation of the tuf gene expression.

We thank Dr H. Weissbach for providing us with purified EF-G, EF-Tu and EF-Ts preparations and antisera against EF-G and EF-Tu; and H. Ahrens, K. Ryan, L. Sadowski, M. Stroud and G. D. Strycharz for technical assistance. This work was supported by grants from the US National Science Foundation and the National Institutes of Health (administered by M.N.) and the National Institutes of Health (administered by R.R.B.). L. L. is a recipient of an EMBO postdoctoral fellowship.

New radio map of Cassiopeia A at 5 GHz

THE radio source Cassiopeia A (Cas A) is believed to be the remnant of a type II supernova that occurred in our galaxy about 280 yr ago (refs 1 and 2). The radio remnant forms an irregular shell of radius $\sim 2'$, corresponding to ~ 1.6 pc at its distance of 2.8 kpc (ref. 2), which is broadly coincident with an incomplete shell of fast-moving optical knots¹. We present here a new radio map of the source with a resolution three times greater than has previously been achieved³.

During November 1974, Cas A was observed with the Cambridge 5-km telescope⁴ at a frequency of 5 GHz, giving half-power beamwidths of $2''$ in right ascension and $2.3''$ in

declination. A total of 128 interferometer spacings were used, so that the synthesised beamshape has its first grating response at $5'$ in right ascension and does not confuse the source. The effective sensitivity is determined by the general level of the side-lobes, which, from regions of the map outside the source, is estimated to have a brightness temperature of 50 K, about 1% of the peak brightness of the source. The sensitivity from thermal noise alone would be 15 K.

Figure 1 shows the map, with contours of the Stokes' parameters I - Q . Figure 2 is a radio photograph showing the finer details not visible at the contour interval (480 K) of Fig. 1. The areas of lower surface brightness are shown very clearly in this negative print, which has 128 separate grey levels.

Fig. 1 Map of Cas A at 5 GHz. The contour interval is 480 K and the coordinates refer to epoch 1950.0

Fig. 2 Radio photograph of Cas A. The grey scales on either side are linear in radio intensity. The features visible at the corners of the map represent the first grating response.

The overall structure of the source is that of a ring, presumably the two-dimensional projection of a spherical shell. The observations show clearly that the brightest part of the ring of emission lies well inside the edge of the source, with a plateau of lower surface brightness outside, as has been noted previously³. This plateau itself shows detailed structure and in many areas seems to provide a well defined outer boundary to the remnant. The most plausible interpretation of these rather sharp boundaries is that they represent the position of a contorted, outer shock front and that relativistic electrons are able to diffuse as far as this shock. The extent of the plateau varies considerably over the remnant. In particular, there is no evidence of any plateau outside the strong peaks to the west of the source.

The ring of brightest emission shows considerable departures from circular symmetry. The well known gaps at position angle (p.a.) 70° and 210° (ref. 3) are less prominent at this resolution and are spanned by weak ridges of emission. There are several small, but clear-cut, gaps in the shell and one of these, at p.a. 200° ($\alpha = 23$ h 21 min 06.3 s, $\delta = 58^\circ 30'45''$), is of interest in relation to the bright knots of emission outside the main ring in this area. One of the new features revealed by the present observations is that the emission within the main ring shows a marked cellular structure defined by weak ridges on scales of $\sim 20''$; towards the edge of the source some of the cells seem flattened, suggestive of foreshortening. Such a cellular structure and the generally chaotic appearance of the remnant is in accord with models of young supernovae^{5,6}, in which the radio shells are first formed as a result of turbulence generated by the interaction between the ejected material and swept-up interstellar medium.

A notable feature of the remnant revealed by this map is the existence of many compact, strongly emitting regions on the scale of the beamwidth, particularly in the sector between p.a. 200° and 310°. Figure 3 is a more detailed contour map of part of the south-west region of the source and shows the proliferation of emission peaks in this area. Projection effects make it impossible to determine the position of most of these blobs relative to the main shell, but those outside

the shell to the south have clearly broken away from it. The radio photograph (Fig. 2) shows a V-shaped feature pointing towards these southern knots. Although this may merely be due to a chance coincidence of knots and filaments, it is reminiscent of a nozzle and we speculate that it represents the remains of that part of the shell from which the outer blobs detached, particularly as its axis coincides with the narrow gap in the bright ring of emission noted earlier. Another such nozzle can be picked out behind the strong, compact emission peaks at the extreme west of the source. Of the southern peaks, the small, slightly resolved, outermost knot at $\alpha = 23$ h 21 min 06.3 s, $\delta = 58^\circ 29'47''$ was not visible in 1969 (ref. 3) and it is intriguing that a recent plate taken by van den Bergh (personal communication) shows that an optical filament has now appeared in this position. This knot seems to have pulled out a neck of plateau in a non-radial direction and indeed all the outlying knots seem to have diffuse emission associated with them. There have also been many other significant changes both of flux and position since 1969 and a detailed study of these will be published elsewhere.

The minimum energy density in relativistic electrons and magnetic field required to account for the radio synchrotron emission from the most compact knots is $\sim 8 \times 10^{-8} \text{ J m}^{-3}$, equivalent to a magnetic field of $3 \times 10^{-7} \text{ T}$. If these knots are to be confined by the thermal pressure of hot, swept-up interstellar gas, then the product $n_H v_3^2$ must be greater than 14, where n_H is the local particle density in the interstellar medium (atom cm^{-3}) and v_3 is the shock velocity (units of $1,000 \text{ km s}^{-1}$). Typical velocities of the fast optical filaments

Fig. 3 Contour map of part of the south-west quadrant of Cas A. The contour level is 480 K.

are $5,000\text{--}7,000\text{ km s}^{-1}$, so containment is not difficult for reasonable values of n_H . Such high pressures, however, imply the existence of a very efficient mechanism for the production of magnetic field.

We thank Professor Sir Martin Ryle and the Staff of the Mullard Radio Astronomy Observatory for advice and assistance. We thank the Electron Microscopy Group of the Cavendish Laboratory, Cambridge, for the use of their Optronics 'Photowrite' System in the production of Fig. 2.

Observations at 6 cm of the solar active region

PRECISE knowledge of the fine structure of radio sources in solar active regions, and especially of their angular size and brightness temperature is important for the gyro-resonance absorption theory of the slowly varying component. In particular, such information is important for verifying proposed models^{1–3} of resonance absorption layers above sunspots for which measurement of circular polarisation is also extremely useful. The active regions at centimetre wavelengths remain stable in intensity and structure for periods of ~ 12 h. Consequently, the existing long baseline interferometers can be used to obtain synthesised maps from observations over those periods. Our first attempt to obtain such maps was in 1973 with the National Radio Astronomy Observatory interferometer at wavelengths of 3.7 and 11.1 cm. These maps were not very clean because of the availability of only three

baselines⁴, a problem which does not arise with the Westerbork synthesis radio telescope, which has twenty baselines. Here we describe the preliminary results of synthesis of a solar active region observed on May 8, 1974 from results obtained on May 8–10, 1974 with the Westerbork synthesis radio telescope (WSRT) in Holland⁵ at a wavelength of 6 cm.

The WSRT consists of twelve 25 m paraboloids along an east–west baseline, combined to form 20 interferometers. For our observations the minimum spacing was 90 m, the maximum 1,458 m, the separation between successive baselines was 72 m and the integration time was 30 s. At the wavelength of 6 cm and for a source with $\delta = 17^\circ$ the WSRT has a synthesised beam size of $6.3''$ (E–W) \times $21.5''$ (N–S) and a primary beam with half width of $10'$. For a single 12-h period of observation the first grating ring has a radius of $3'$ (E–W) and $10'$ (N–S). In spite of the presence of several sources in the field of view, the associated grating rings were successfully removed from the maps by using conventional 'cleaning' techniques⁶. Because baselines smaller than 90 m are missing, the instrument eliminates a considerable fraction of the flux of sources with size greater than $1'$ (E–W) \times $3'$ (N–S).

There are two major problems with a sidereal instrument used for solar observations: appropriate source tracking and receiver saturation. As the WSRT tracks at sidereal rate, we had to update the pointing of the dishes every 30 min. The difference between solar and sidereal motion over this interval (30 min) is about $0.6'$, which is comparable with the pointing error of the dishes. The phase drift of the visibility function due to solar motion was corrected in the data processing stage by a standard WSRT reduction routine. The accuracy of the tracking obtained this way is better than the synthesised beam width. Because of perspective changes caused by solar rotation during the 12-h observing period, however, only the region near the centre of the field of view can be tracked accurately. To avoid receiver saturation, an extra attenuation of about 25 dB was placed in front of the correlators. This attenuation was removed during calibration. The input of each correlator was adjusted to a constant level, the same for all correlators and all observations (solar and calibrator).

The instrument was used for 12 h of solar observation and 12 h of calibration each day. The sources 3C286, 3C147 and 3C48 were used for phase calibration and 3C147 for amplitude calibration. The accuracy of the phase calibration is better

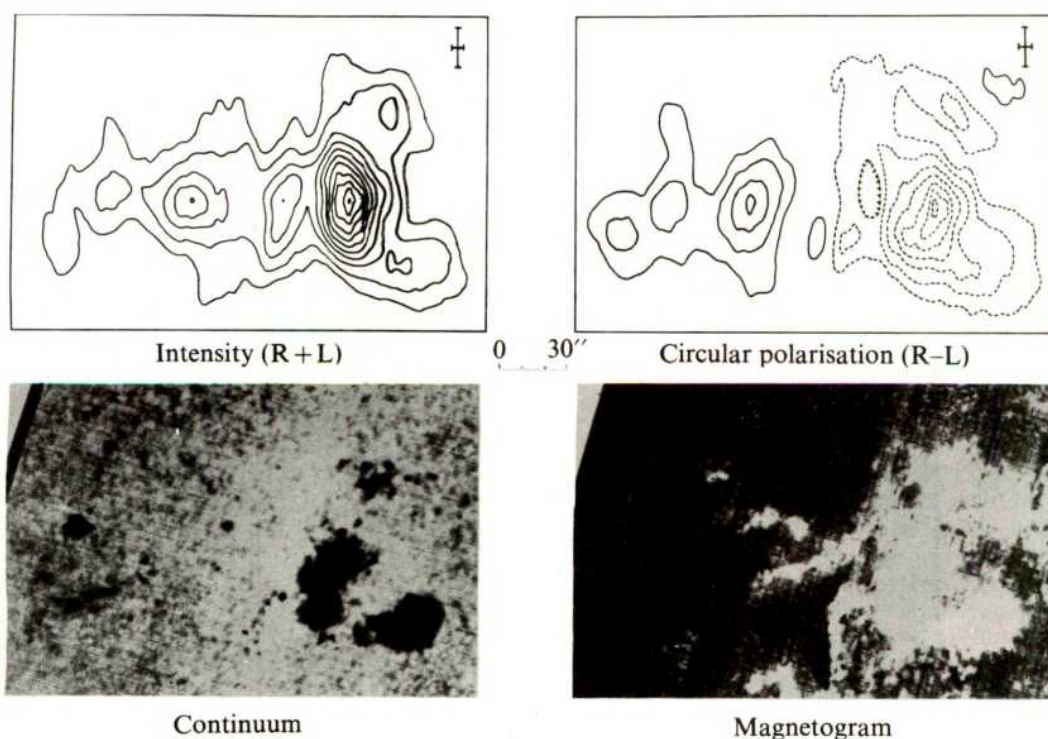

Fig. 1 Total intensity and circular polarisation maps of an active region near S12W05 on May 8, 1974. The beam size is shown in the upper right-hand corner. Contour levels are: 0.1, 0.25, 0.50, 0.75, 1.00, 1.25, 1.50, 1.75, 2.00, 2.25, 2.50 ($\times 10^6$ K) for $R+L$; $-0.750, -0.625, -0.500, \pm 0.375, \pm 0.250, \pm 0.125, \pm 0.050$ ($\times 10^6$ K) for $R-L$. Negative contours are shown by broken contour lines. The hatched contour on the $R-L$ map shows a decrease of the absolute value of the polarisation. Continuum photograph and magnetogram courtesy Sacramento Peak Observatory, AFCRL. Positive magnetic field is white.

Fig. 2 A burst observed on May 9, 1974 with the WSRT: *a*, Flux (arbitrary units) as observed with a single Westerbork dish. *b*, Contours of equal circular polarisation (L-R) as a function of east-west position and time. Contour levels are: 0.29, 0.58, 0.87, 1.16, 1.45 and $1.74 (\times 10^7 \text{ K arc s})$. The peak values are 1.85×10^7 , 1.20×10^7 and $0.73 \times 10^7 \text{ K arc s}$ for the first, second and third peak respectively. The numbers indicate the percentage polarisation of the peaks. *c*, Equal intensity contours (L+R) as a function of east-west position and time. Contour levels are: 1.7, 3.4, 5.1, 6.8, 8.5, 10.2 and $11.9 (\times 10^7 \text{ K arc s})$. The peak values are 7.1×10^7 , 6.9×10^7 and $12.1 \times 10^7 \text{ K arc s}$ for the first, second and third peak respectively. The arrows in *b* and *c* show the position of the associated active region at S07W37. The response of constant sources has been subtracted from *b* and *c*.

than 1° , and the amplitude calibration is accurate to about 4%. The amplitude error is higher than the customary 1% in other WSRT observations because of the extra attenuation.

The data were calibrated and Fourier transformed by using standard WSRT reduction programs. The resulting 'dirty' maps were cleaned of sidelobes at the University of Maryland. All four Stokes parameters were observed, but the linear polarisation maps have a very noisy appearance, which puts the linear polarisation limit at about 2%. A total intensity and circular polarisation map from May 8 is shown in Fig. 1, together with a white light photograph and a magnetogram from Sacramento Peak Observatory. The coordinates of the sunspot group at 0 UT were S12W05. This group is part of McMath region 12906, which had a very extended plage.

Several individual sources show up in both total intensity and circular polarisation maps. The brightest source with a peak temperature of $2.5 \times 10^6 \text{ K}$ corresponds to one of the two large sunspots. The emission is extended northwards to the group of small sunspots, south-west towards the other large sunspot and eastward towards another group of small sunspots. The other three sources are overlying the plage with the brightest component located close to the neutral

line of the magnetic field. A low brightness halo surrounds the sources. The halo has a brightness temperature of about 10^5 K . It does not, however, extend over the entire plage region. This is probably because the interferometer spacings less than 90 m were not available for our observation.

As shown in the magnetogram, the active region has a bipolar structure with positive polarity concentrated on the main sunspots and negative polarity scattered over the plage and some minor sunspots. H α photographs show filaments along the neutral line. The circular polarisation map closely follows this configuration, with regions of positive magnetic polarity having the strongest degree of left circular polarisation. It is interesting to note that the source just to the east of the main peak lies along a neutral line and has a bipolar circular polarisation structure.

During our three days of observations several bursts were recorded. Because of the short lifetime of the bursts, it is not possible to produce a two-dimensional map with the interferometer. But, as the 20 baselines of the WSRT are located along a straight line, it is easy to combine them and produce the equivalent of a fan beam scan. This one-dimensional intensity distribution is displayed in Fig. 2 for a burst observed on May 9. We have used a contour map display, with the intensity shown as a function of position and time. For the sake of clarity we have subtracted the response of the constant sources. Our resolution is about $6''$ in the east-west direction; the integration time is 30 s. Figure 2 also gives the flux of the burst as recorded by a single Westerbork dish.

This particular event corresponds to an H α flare⁶ of importance 1B at S05W38. The flare occurred near a sunspot group shown by an arrow in Fig. 2. The burst shows three distinct maxima, the third and brightest of which coincides in time with the reported optical maximum. The east-west size of the burst during this maximum is $12''$; assuming the same north-south size we obtain a peak brightness temperature of 10^7 K . This particular peak is about 6% left circularly polarised. The other two peaks have lower brightness temperatures but are more strongly left circularly polarised; the polarisation is of the same sense as that of the associated active region. The position of the maximum emission changes with time, which cannot be due to the change of baseline because this change is very small, indicating that the position of the burst changes during its lifetime.

We thank the Program Committee of WSRT for time on the telescope, Messrs Bregman and Hin for much assistance during the observations and Dr H. Van Someren Greve for help during the initial period of data reduction. We also thank Dr J. van Nieuwkoop and members of WSRT technical group for assistance before the observations, Dr P. Lantos for participating in the observations, and the Leiden and Westerbork observatories for their warm hospitality during our stay. This work was supported by grants from NASA and the NSF. Computer time was supported in part by a NASA grant to the Computer Science Center of the University of Maryland. The Westerbork Radio Observatory is operated by the Netherlands Foundation for Radio Astronomy with the financial support of the Netherlands Organisation for the Advancement of Pure Research (ZWO).

Special relativity and very long baseline interferometers

WHEN baseline lengths approach the diameter of the Earth, relativistic effects become important, especially in geodetic applications. Failure to take account of these effects results in errors that are equivalent to clock errors of the order of a few parts in 10^{12} .

One method of making the correction has been to use a geocentric coordinate system for the purpose of working out the classical Doppler shift and then to multiply this by a time-dilatation term involving the difference in axial distances between the two receivers. This procedure leads to an erroneous result¹.

The correct approach involves the use of two coordinate systems. One is the source frame of reference and the other is the frame of reference of one of the receivers. To avoid repetition, a table of symbols with their definitions is given in Table 1. The symbols (U) and (O) in the right hand column denote unobservable and observable quantities, respectively. The object of the calculations presented here is to recast an equation involving unobservables into one containing only observables.

Table 1 Definition of symbols

Symbol	Definition
\mathbf{v}_1	(U)* Velocity of receiver 1 relative to source (Source frame)
\mathbf{v}_2	(U) Velocity of receiver 2 relative to source (Source frame)
\mathbf{l}	(U) Unit vector in direction of Earth as seen from source (Source frame)
\mathbf{l}_1'	(O)* Unit vector in direction of the source as seen from receiver 1 (Receiver 1 frame)
\mathbf{l}_2'	(O) Unit vector in direction of the source as seen from receiver 2 (Receiver 2 frame)
α_1	(U) Angle between \mathbf{v}_1 and \mathbf{l} (Source frame)
α_2	(U) Angle between \mathbf{v}_2 and \mathbf{l} (Source frame)
α_1'	(U) Angle between \mathbf{v}_1 and \mathbf{l}_1' (Receiver 1 frame)
\mathbf{V}	(O) Velocity of receiver 2 relative to receiver 1 (Receiver 1 frame)
ϕ_1'	(O) Angle between \mathbf{l}' and \mathbf{V} (Receiver 1 frame)
ϕ_2'	(O) Angle between \mathbf{l}_2' and \mathbf{V} (Receiver 2 frame)
ν	(U) Frequency emitted by source
ν_1'	(O) Frequency received at receiver 1
ν_2'	(O) Frequency received at receiver 2
c	Velocity of light

*U, Unobservable and O, observable quantities.

Except for \mathbf{V} , the velocity of receiver 2 relative to receiver 1, unprimed quantities are in the source frame of reference, and thus unobservable, and primed quantities are in the frame of reference of receiver 1. The receivers need not be Earth-bound, but the source and receiver frames are treated as inertial systems.

Following Pauli², the source coordinate axes are arranged so that the x axis is in the direction of \mathbf{v}_1 . The y axis is in the plane of \mathbf{v}_1 and \mathbf{l} and the z axis is perpendicular to x and y . The coordinate axes of receiver 1 are parallel to the source axes, but the two systems are in uniform motion relative to one another. The basic equations to be considered are:

$$\nu_1' = \nu \frac{1 - (v_1/c) \cos \alpha_1}{\sqrt{1 - (v_1^2/c^2)}} \quad (1)$$

and

$$\nu_2' = \nu \frac{1 - (v_2/c) \cos \alpha_2}{\sqrt{1 - (v_2^2/c^2)}} \quad (2)$$

These are the relativistic Doppler equations applied to the two receivers. Equation (2) can, however, be recast. The vector \mathbf{v}_2 is the sum of \mathbf{v}_1 and \mathbf{V} ; \mathbf{v}_1 is, however, in the source frame of reference and \mathbf{V} is in the frame of reference of receiver 1 so that it is necessary to resort to the relativistic summation of velocities. The cartesian components of \mathbf{v}_2 are, therefore:

$$\left. \begin{aligned} v_{2x} &= \frac{V_x + v_1}{1 + (V_x v_1/c^2)} \\ v_{2y} &= \frac{\sqrt{1 - (v_1^2/c^2)}}{1 + (V_x v_1/c^2)} V_y \\ v_{2z} &= \frac{\sqrt{1 - (v_1^2/c^2)}}{1 + (V_x v_1/c^2)} V_z \end{aligned} \right\} \quad (3)$$

α_2 is the angle between \mathbf{v}_2 , whose direction cosines are v_{2x}/v_2 , v_{2y}/v_2 , v_{2z}/v_2 , and \mathbf{l} , whose direction cosines are $\cos \alpha_1$, $\sin \alpha_1$, and 0. Therefore:

$$v_2 \cos \alpha_2 = v_{2x} \cos \alpha_1 + v_{2y} \sin \alpha_1 \quad (4)$$

The denominator of equation (2) is $\sqrt{1 - (v_2^2/c^2)}$, where $v_2^2 = v_{2x}^2 + v_{2y}^2 + v_{2z}^2$.

Using equation 3:

$$\sqrt{1 - (v_2^2/c^2)} = \frac{1}{1 + (V_x v_1/c^2)} \sqrt{\{1 - (V^2/c^2)\}[1 - (v_1^2/c^2)]} \quad (5)$$

Using equations (1), (3), (4), and (5) in (2):

$$\nu_2' = \frac{\nu_1'}{\sqrt{1 - (V^2/c^2)}} \times \left[1 - \frac{\{(V_x/c)(\cos \alpha_1 - (v_1/c)) + (V_y/c)\sqrt{1 - (v_1^2/c^2)}\} \sin \alpha_1}{1 - (v_1/c) \cos \alpha_1} \right] \quad (6)$$

From Pauli²:

$$\frac{\cos \alpha_1 - (v_1/c)}{1 - (v_1/c) \cos \alpha_1} = \cos \alpha_1'$$

and

$$\frac{\sqrt{1 - (v_1^2/c^2)} \sin \alpha_1}{1 - (v_1/c) \cos \alpha_1} = \sin \alpha_1'$$

Therefore:

$$\nu_2' = \frac{\nu_1'}{\sqrt{1 - (V^2/c^2)}} \left[1 - \frac{V}{c} \left(\frac{V_x}{V} \cos \alpha_1' + \frac{V_y}{V} \sin \alpha_1' \right) \right] \quad (7)$$

$(V_x/V) \cos \alpha_1' + (V_y/V) \sin \alpha_1'$ is $\mathbf{V} \cdot \mathbf{l}'$. Therefore:

$$\nu_2' = \frac{\nu_1'}{\sqrt{1 - (V^2/c^2)}} \left[1 - \frac{V}{c} \cos \phi_1' \right] \quad (8)$$

Equation (8) is the required equation. It expresses the frequency received at one receiver in terms of the frequency received at the other. It contains only observables. ϕ_1' is the angle between the source direction measured from receiver 1, and the velocity of receiver 2 relative to receiver 1. The term

$(V/c) \cos \phi_1'$ is similar to the classical Doppler term, but the angle ϕ_1' involves the source direction as seen from receiver 1 and so includes diurnal aberration. If a geocentric coordinate system had been chosen, the Doppler term could not have included diurnal aberration. $1/\sqrt{1-(V^2/c^2)}$ is a time-dilatation factor, and the right hand side of equation (8) is the product of a time-dilatation and a Doppler shift factor; all of the terms must be defined correctly.

It makes no difference which receiver is labelled number 1, and, therefore, equation (8) can equally well be written

$$v_1' = \frac{v_2'}{\sqrt{1-(V^2/c^2)}} \left[1 - \frac{V}{c} \cos \phi_2' \right] \quad (9)$$

From equations (8) and (9):

$$\cos \phi_2' = - \frac{(\cos \phi_1' - (V/c))}{1 - (V/c) \cos \phi_1'} \quad (10)$$

Equations (8) and (10) have the same form as equations (15) and (16) of Pauli². These are the relativistic Doppler equation and the equation for transforming angles from the source frame to the receiver frame of reference. In the simple Doppler case involving one source and one receiver, however, the velocity involved is the relative velocity between source and receiver, whereas in my equations (8) and (10), the velocity involved is the velocity of one receiver relative to the other one. The velocity of the source relative to the receivers, which is unobservable by means of an interferometer, is not involved.

Mode of propagation of penumbral waves

THE solar atmosphere provides an interesting possibility for the study of low frequency waves both in magnetic and non-magnetic regions, and the most spectacular result (see ref. 1) has been the discovery of waves propagating outwards over sun-spot penumbrae with periods of 180–240 s, horizontal wavelengths of 2,350–3,800 km, and horizontal phase velocities of 12–25 km s⁻¹. The theoretical interpretation of these waves has aroused considerable interest and, in particular, a number of authors have attempted to identify the precise mode of wave propagation involved. The modes proposed include Alfvén waves¹, acoustic waves², Lamb waves³, and magnetogravity waves of the 'plus' type vertically trapped at photospheric levels⁴. In the face of so many possibilities, further progress will probably depend on a more adequate observational knowledge of the actual propagation characteristics of the penumbral waves. Of special importance would be a determination of the direction of the particle velocity with respect to the wave propagation vector.

I have therefore explored the conditions of observability as a function of heliocentric angle for purely longitudinal (that is, particle velocity parallel to the propagation vector) and purely transverse (that is, normal to the propagation vector) waves and I present here observations that tend to support a predominantly longitudinal mode of wave propagation.

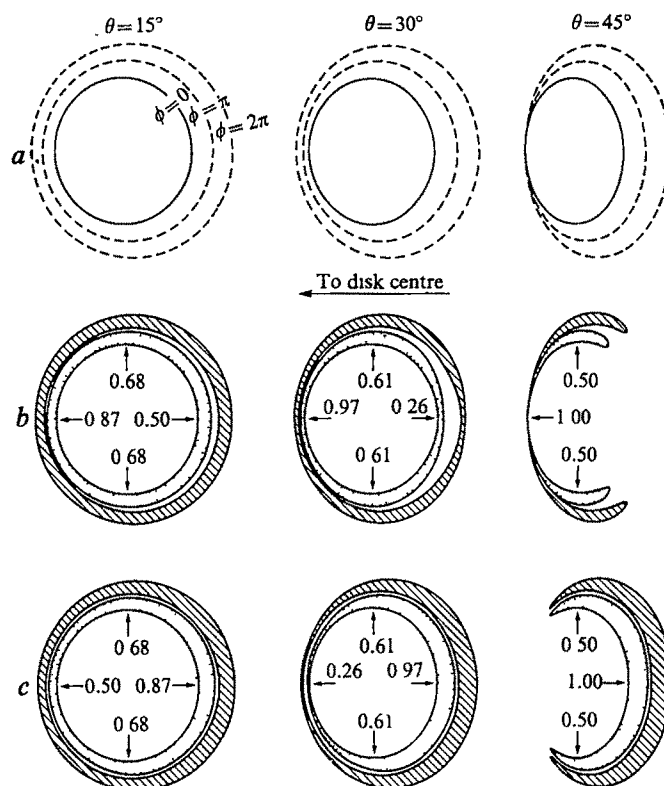

Fig. 1 *a*, Loci of positions with phase $\phi = 0, \pi$, and 2π in a hypothetical wave pattern (see text) for different values of the heliocentric angle θ . The wave is assumed to propagate at an angle $\alpha = \pi/4$ with respect to the vertical. Regions with line-of-sight velocity $|v_{||}| > 0.25v_0$, where v_0 is the amplitude of the wave, are shown for longitudinal waves (*b*), and transverse waves (*c*). The maximum line-of-sight velocity (in units of v_0) is given for certain position angles. Shaded and hatched regions refer to receding and approaching velocities, respectively.

Consider a hypothetical, progressive wave symmetrical with respect to the spot axis, such that at a fixed instant of time the horizontal distance from the centre of the spot is equal to r for positions in the wave with phase $\phi = 0$ and $r + \lambda \sin \alpha$ for $\phi = 2\pi$. Here, λ is the wavelength of the wave, assumed to propagate at an angle α with respect to the vertical. Projected on to a plane perpendicular to the line of sight, the loci of positions in the wave with $\phi = 0$ and 2π represent ellipses. The $\phi = 2\pi$ ellipse is displaced by an amount $\lambda \cos \alpha \sin \theta$ towards the solar limb with respect to the $\phi = 0$ ellipse. Positions in the wave with $\phi = 0, \pi$, and 2π are shown in Fig. 1*a* for different values of the heliocentric angle θ , assuming $\alpha = \pi/4$, $r = 6,500$ km, and $\lambda \sin \alpha = 3,000$ km. As the wave propagation vector is observed to have a horizontal component, a value of α close to zero cannot account for the observations, but a determination of α is not available at present.

Depending on the type of wave involved, variations in the line intensity may⁵ or may not⁶ occur. The line intensity is not a simple function of the particle velocity in the wave. But provided that the wave amplitude is independent of position angle in the spot, positions with the same phase will also show the same line intensity. The appearance of an 'intensity' wave at different heliocentric angles can, therefore, be visualised from Fig. 1*a*, which shows lines of equal phase.

For a longitudinal wave the particle velocity, v , has the components $v \sin \alpha$ and $v \cos \alpha$ in the horizontal and the vertical directions, respectively, whereas for a transverse wave the corresponding components are $-v \cos \alpha$ and $v \sin \alpha$. Assuming that the velocity amplitude v_0 is constant across the region $\phi = 0-2\pi$, we have calculated the line-of-sight velocity $v_{||}$ of the particles in the wave using the equations given by Maltby⁷. The results are given in Fig. 1*b* and *c* which shows the regions

where $|v_{||}|$ exceeds $0.25v_0$ for longitudinal and transverse waves, respectively.

The direction of particle motion in the waves can be studied by comparing observations of spots situated close to the limb with those of spots near the disk centre. Observations of sunspots at large heliocentric angles are, however, hampered because of foreshortening. On the other hand, Fig. 1*b* and *c* indicates that significant differences in the observability of longitudinal and transverse waves still exist for spots situated at intermediate heliocentric angles. The observability of the waves evidently depends on the direction of wave propagation (that is, on the value of α). If $\pi/4 < \alpha < \pi/2$, transverse waves are observable more easily than longitudinal waves in spots situated near the disk centre.

We have compared hypothetical wave patterns with actual wave patterns observed in spots photographed at the Commonwealth Scientific and Industrial Research Organisation (CSIRO) Solar Observatory, Culgoora, between 1971 and 1974. No asymmetry was detected in six spots situated relatively close to the centre of the solar disk ($\theta < 23^\circ$). For the spots observed on November 3, 1971 (ref. 1: Fig. 1) and July 3, 1973 (ref. 8: Figs 1–4) penumbral waves are practically absent on the limb side of the spot, but prominent in other places; these spots have heliocentric angles of 35° and 34° , respectively. The observed asymmetries therefore tend to support an interpretation in terms of a predominantly longitudinal mode of wave propagation. The available data are, however, very limited and more observations will be required before any firm conclusion can be reached.

I thank Dr R. G. Giovanelli for allowing me to inspect his sunspot films and E. J. Tappere and N. Bryant for observational assistance.

Basal complex of Fuerteventura (Canary Islands) is an oceanic intrusive complex with rift-system affinities

THE exposed portions of the Canary Islands largely comprise Cainozoic volcanic rocks erupted sub-aerially in successions essentially specific to each island, though with somewhat complex interrelationships¹. On three islands, Fuerteventura, La Palma, and Gomera these rocks rest unconformably on older formations which are similar enough to suggest that a common basement may exist. The largest area of the basement complex rocks is the Betancuria Massif^{2–4}, Fuerteventura. Gastesi⁴ has suggested that similarities exist between the Betancuria Massif and other ophiolite complexes (such as the Troodos Massif of Cyprus^{5,6}) generally held to be representative of oceanic crust formed at certain constructive plate margins.

The most obvious feature of the complex is the striking dyke swarm in which the dyke intensity sometimes reaches 100%. The oldest rocks seen at the present erosion level form the host rock to the dyke swarm and comprise basic and alkaline rocks of plutonic aspect together with marine sedimentary rocks intercalated with submarine volcanics (Table 1*a*). The sediments comprise laminated shales and

*Date from a reinvestigation conducted during 1974, and recent work by the Instituto Lucas Mallada.

siltstones, turbiditic sandstones and thin tuffs and limestones; Cretaceous foraminifera have also been found⁷. Weak regional metamorphism and metasomatism have affected all the strata; in addition, the sediments close to the ultrabasic and basic intrusions (Table 1*c*) have been thermally metamorphosed. Deformation has imposed a regional cleavage and much of the observed sequence is inverted by large scale, WNW–ESE trending folds. According to Rothe⁷ these rocks are similar to rocks from the African continent and from Maio in the Cape Verde Islands. At the top of the sedimentary sequence interbedded hyaloclastites and pillow lavas appear, leading up into a thick series of submarine volcanics in which both basaltic and trachytic types are represented. The bedded volcanic rocks are traversed by synchronous sheet intrusions of similar petrography to the pillow lavas.

Because of the subsequent intrusion of a dyke swarm it is difficult to trace stratigraphic continuity. It seems, however, that tuffs become much more common passing upwards: calcareous tuffs appear with thin limestones which become more frequent until thick fragmental limestones containing abundant shell debris are seen. Fossils of Miocene to Eocene age have been recorded from this horizon⁸. It seems that these sediments are of shallow water origin, and according to earlier work² the sequence continues upwards into subaerial tuffs and agglomerates. In the reinvestigated area the succession is terminated by an unconformity above which the Basalt Series was erupted.

In the south-western part of the Betancuria Massif, the host rocks to the dyke swarm comprise basic and alkaline rock of plutonic aspect. The relationship between these rocks and the Mesozoic bedded rocks is not clear as the contact is obscured by the younger dyke swarm. Intruding both the plutonic and the bedded rocks are abundant veins and occasional small intrusive bodies of syenite and small carbonatite dykes which occupy a zone marginal to the plutonic rocks and which do not extend far into the sediments and submarine volcanics.

All of those rocks are traversed by a swarm of dominantly basaltic and ankaramitic dykes with a general NNE–SSW trend (Table 1*b*). The swarm contains dykes of several ages, but the majority belong to a major phase of permissive emplacement which involved no deformation of the host rock other than distension of the crust. Throughout this phase of emplacement later dykes injected earlier ones and, consequently, individual dykes may be dismembered, with the fragments widely separated. Both the host rocks and dykes of this phase show the imprint of a greenschist facies metamorphism and, as in the oceanic greenstones, are typically devoid of a pervasive foliation⁹. The recognition of thermal aureoles around basic and ultrabasic bodies

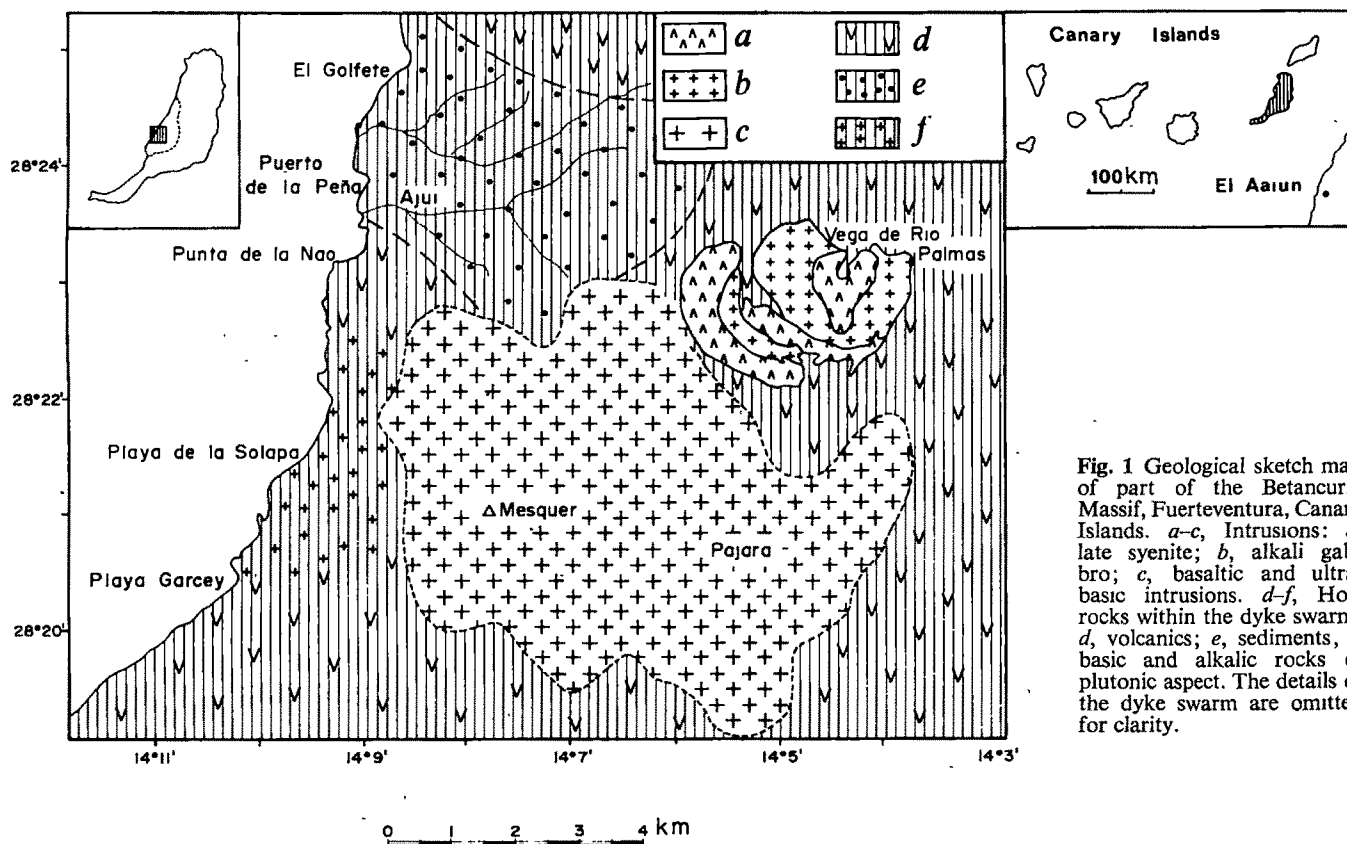

Fig. 1 Geological sketch map of part of the Betancuria Massif, Fuerteventura, Canary Islands. *a-c*, Intrusions: *a*, late syenite; *b*, alkali gabbro; *c*, basaltic and ultrabasic intrusions. *d-f*, Host rocks within the dyke swarm: *d*, volcanics; *e*, sediments, *f*, basic and alkalic rocks of plutonic aspect. The details of the dyke swarm are omitted for clarity.

(Table 1c) which intrude the earlier parts of the complex has made possible the distinction of at least two periods of dyke intrusion in the main phase. The proportion of dykes to host rock increases markedly towards these younger intrusives, implying that during emplacement basaltic magmas from the intruding body was fed actively into fractures within the overlying crust and that it was into that heavily dyked host that the pluton was finally emplaced. The older dykes (whose parent pluton is not exposed at the present erosion level) and those associated with the more recent activity are petrologically similar, are affected by the same greenschist facies metamorphism, and strike in the same direction. The field evidence thus suggests repeated plutonic and hypabyssal intrusion in the same environments within a single extensional stress field.

Subsequent to the relaxation of this stress field, sheet intrusions associated with still later syenitic and trachytic ring complexes were emplaced into the dyke swarm. In addition, younger, zeolite facies basaltic dykes of unknown affinities also occur.

Most of the later dykes follow the same trend as the earlier ones where the dyke intensity approaches 100% though the concordance is much less noticeable away from this zone. Apparently, the initial trend was dictated by regional tensional stresses, but subsequent emplacement was controlled more by the grain imposed on the crust by the dyke swarm. Some of the ultrabasic and gabbroic intrusions are parallel to the orientation of the dyke swarm, others have been emplaced by passive stoping, sometimes associated with ring fracturing. The latter are succeeded by syenite and trachyte intrusions which form large partial ring dykes and sheet intrusions such as those at Vega de Río Palmas.

Although the individual components of the Basal Complex, are similar to those forming ophiolites^{4,10}, the relationships which define an ophiolitic terrain¹⁰ are not seen, and it is, therefore, uncertain whether the Basal Complex represents a fragment of normal oceanic crust. There can be little doubt that the bedded rocks were erupted and de-

posited on an ocean floor; but the problem remains. was this part of a marginal basin underlain by continental crust or was it part of the new Atlantic crust? The bedded rocks range in age from the Upper Cretaceous⁷ to the Mid-Tertiary⁸, though that range may be more extensive—Rothe⁷, for example, has suggested that the older sediments may be Jurassic, and that the Mesozoic rocks at least have been involved in Alpine-style tectonics, and are, therefore, presumably related to the Atlas tectonism on the African continent. Further evidence that the sediments form part of a continental margin basin is provided by seismic profiles from the area between Fuerteventura and the mainland, which indicate the presence of some 10 km of sediment¹¹. There is, however, a divergence of opinion as to the nature of the crust beneath these sediments^{2,11-14}. Further, although seismic data confirm the existence of an important fracture west of Fuerteventura^{13,14} there seems to be little in the available petrological and geochemical data to suggest that the islands in the west and east of the archipelago are emplaced over significantly different crust. Data from the basal complexes do not indicate much difference in the early stages, and studies^{15,16} of Cainozoic magmas reveal inter-island relationships which are complex, and do not suggest any particular relationship between geochemistry and distance from the African continent.

Radiometric data suggest that the majority of the Fuerteventura Basal Complex intrusives were emplaced in mid-Tertiary times. Ages from dykes of the main phase range from 32 Myr to 46 Myr; the age of the older basic and alkalic rocks of plutonic aspect is not yet known, and the only pluton which has so far been dated (20 Myr) is one of the youngest: the outer ring syenite of the Vega de Río Palmas Complex (ref. 17, and D. Rex and I. G. Gass, personal communication). Basal Complex activity must have terminated shortly after 20 Myr BP, as the beginning of subaerial volcanicity has been dated at >16.5 Myr (ref. 17).

The tensional conditions which permitted the intrusive phase on Fuerteventura may well represent mid-Tertiary

rifting and may indicate the existence of an embryonic spreading axis which aborted after a relatively short time, a view already postulated by Gastesi⁴. The extensional stress field had probably relaxed by the time of emplacement of the syenite ring complexes approximately 20 Myr BP. The variations in trend of the Basal Complex dyke swarms on La Palma, Gomera and Fuerteventura may indicate several 'spreading' attempts but until more precise chronological correlation is possible, that remains speculative. The case for a propagating fracture model to explain the continuing volcanicity of the Canary Islands has been propounded¹, and the proposed model for mid-Tertiary rifting does not conflict with that idea.

This work is a preliminary report of a joint research project led by Professor J. M. Fuster of Madrid and Professor I. G. Gass of the Open University, UK. The British members of the project acknowledge financial support from the National Environment Research Council. We also thank A. Hernandez Pacheco, F. Anguita, F. Hernan and J. M. Navarro, I. G. Gass, M. J. Le Bas, P. Gastesi and A. Cendrero for field assistance and discussions.

Fig. 1 The Nazca Plate showing DSDP sites 319, 320, 321 and 157.

that the determination of the ages of sites 319 and 320 with respect to the magnetic reversal time scale will be precluded. Table 1 shows the basement ages for the sites, estimated from the overlying sediments.

The total penetration of basement rocks at three sites was 105 m, of which only 15 m were recovered for study. A total of 35 basalt and 32 sediment samples (vertically oriented) was taken from the leg 34 drill sites. In addition, we have studied four samples from site 157 of the DSDP leg 16, also on the Nazca Plate.

Recovery of coarse grained massive basalts at several sites, in addition to pillow sequences, justifies the previous suggestion⁴ that dredged material from the upper surface of oceanic layer 2 is unrepresentative of the layer as a whole. Coring in the massive flow units produced good recovery at sites 319 and 321, and pillow material resulted in poor recovery at all sites. Table 1 shows the average natural remanent magnetisation (NRM) intensity for each site, weighted for the differential recovery of fine and coarse material. Pillow material was significantly less intensely magnetised than the coarse grained flow interiors, and this is shown by comparison of the average magnetisation at sites 321 and 157, which were dominated by

Magnetic results from basalts and sediments from the Nazca Plate

THE drilling sites for leg 34 of the Deep Sea Drilling Project (DSDP) were in the Nazca Plate (Fig. 1), which was formed by the spreading from two ridges, the fossil Galapagos Rise and the currently active East Pacific Rise. Spreading half rates on the East Pacific Rise vary from 8 to 10 cm⁻¹ (refs 1-3) and are the highest on any presently active ridge. Fast spreading is associated with subducted basement topography, a situation that enables structural provinces within the Nazca Plate to be clearly delineated. The near equatorial latitudes of the sites with poor magnetic anomaly development mean, however,

Table 1 Basement ages and average intensity of undemagnetised natural remanent magnetisation for the basement basalts

Site	Estimated age of sediment directly above basement (Myr)	Site average NRM intensity (e.m.u. cm ⁻³ × 10 ⁻⁴)	
		Averaged over all NRM values	Weighted for differential recovery of fine and coarse grained basalts

coarse grained material, and site 320, which was exclusively oxidised pillow basalts. Site 319 is a 60-m basement section, and the remanence is dominated by a 10–20-m section of coarse grained flow material.

For the basalt samples, the ratio of remanent intensity to induced magnetisation, Q , was in all cases greater than 1. The range of Q was large, for massive flows varying from 2 to 28 and for fine grained basalts varying from 2 to 56. It would seem that for these samples, the remanent intensity will be dominant.

The coarse grained basalts of hole 319A had very large, soft components of magnetisation that were directed vertically upwards. This hole was drilled with a magnetic steel drilling assembly, a configuration that is sometimes responsible for a drilling remanent magnetisation. Lowrie and Kent⁵ have shown that for some of the leg 34 coarse grained samples, exposure to a field as small as 4 oersted for only a few hours, a time sufficient to drill 9.5 m of basalt, can generate the observed soft components. The massive flow basalts of site 321, which were drilled with a non-magnetic monel metal drilling assembly, had soft secondary components of magnetisation which were directed downwards. At all of the leg 34 sites, the geomagnetic field, at present, is inclined upwards at a shallow angle. The soft components of NRM measured in the laboratory seem to be some combination of drilling and viscous remanent magnetisation (VRM) acquired on the ocean floor. Lowrie and Kent⁵ have also shown that these coarse grained samples can acquire a VRM component that is comparable in intensity with the stable component in less than 7×10^5 yr. If this is the case, then *in situ* VRM will be the dominant remanence and should mask or distort any stable thermoremanent magnetisation (TRM). In areas of the oceanic crust which are predominately coarse grained basalts, the magnetic anomaly which is evident at the sea surface will be composed of some combination of a viscous remanence, the induced magnetisation (both in the direction of the present field), and the original thermoremanence. In these areas, the magnetic anomalies will tend to be positive, and the variations in the anomaly pattern will be unlikely to correspond to a magnetic reversal time scale.

Table 2 shows the inclinations for the partially demagnetised basalt samples, averaged for each site. The values for sites 320 and 321, the oldest sites, are close to those expected for an axial

centred dipole at the latitude of each site. Sites 157 and 319, however, show significant departures from the inclinations expected at the present-day latitudes of the sites. Interpretation of these inclinations as actual palaeolatitudes would require unusually large plate velocities of 20 cm yr⁻¹ and would also require that the Nazca Plate moved rapidly southward between 26 and 15 Myr ago, and then northward to the present latitude between 15 Myr ago and the present.

A more reasonable explanation is that the basalts taken at sites 157 and 319 were erupted over a time interval that was too short to average over a quasi-period (10^3 yr) of secular variation. A possible, but less likely explanation is that during extrusion, the geomagnetic field was undergoing a polarity transition or some systematic deviation. Tectonic movement of crustal blocks, although present to a small extent, is an unlikely cause of the rotation of the magnetic directions. Chemical remagnetisation due to oxidation can be eliminated since similar directions are indicated for both the oxidised and unoxidised samples. The tight and consistent grouping of the inclinations of site 319 indicates that a short period of extrusion is the likely explanation.

Additional information about the palaeolatitude of the Nazca Plate is available from the sediments which overlie the basement basalts. Since the sedimentation rate in this area has been estimated to be 2.8–4.2 cm every thousand years⁶, each sediment sample with a diameter of 1.9 cm covers about 450–680 yr. At each site, the sediment column directly above the basement was cored over a few tens of metres, a thickness representing about 10^6 yr. When the sampling interval is extended over this longer time period, the sediment inclinations in Table 2 show a southward palaeolatitude change of 3–5° for the Nazca Plate during the past 15 Myr and no latitude change between 15 and 40 Myr BP. This agrees with previous studies^{1–3,6} that the motion of the plate has been largely in an eastward direction.

The study of the palaeomagnetism of oceanic basement rocks can provide information regarding a rough minimum of the amount of time involved in crustal genesis. The presence of several magnetic reversals in a column of basalt flows implies a time of formation of 10^5 – 10^6 yr or greater, whereas a tight grouping of inclinations of a single polarity (that deviate

Table 3 Comparison of rock magnetic parameters for site 319

Samples were grouped into one of three categories for comparison of parameter variation with low temperature oxidation state and grain size

*Numbers in parentheses are number of samples

significantly from the expected inclination) may imply extrusion within 10^2 yr. The inclination data from site 319 suggest that the basement crust sampled at this site was formed in a relatively short time. Too few oriented samples were recovered from site 320 for any interpretation to be made. The inclinations from site 321 were tightly grouped with the exception of one reversed inclination from a sample at the very top of the basement section. Re-examination of the drill core showed that this section had been inverted during drilling. If this reversal is the result of coring, then the column of basement basalts at this site would also have been generated over a short ($\leq 10^2$ yr) time period. At site 157 the three top samples were normally magnetised and overlie a reversely magnetised sample. Re-examination of the drill core showed no evidence that this reversal was the result of drilling. If this bottom sample represents a true field reversal, then this column of basement basalts is recording a period in which the geomagnetic field is reversing or the time of formation of this thin layer of ocean crust is greater than 10^5 – 10^6 yr.

The basalt samples were divided into three categories, based on the size of the titanomagnetite grains present and the degree of alteration of these grains by low temperature oxidation.

(1) The first category consists of the unoxidised interiors of massive volcanic units characterised by large unoxidised titanomagnetite grains, 20–30 μm in mean size with grains up to 100 μm .

(2) Second, there are samples similar to the first, but now oxidised to titanomagmaemite and physically subdivided by cracks due to alteration.

(3) Lastly, there are fine grain pillow basalts with skeletal grains of titanomagmaemite, 2–5 μm in size. No unoxidised pillow material was recovered.

Division of the basalt samples into these categories makes possible the correlation of the magnetic parameters with low temperature oxidation state and grain size. Data from Site 319, which contained all three types of basalt samples, enable comparisons to be made without a wide variation in age or geographic location. Table 3 shows the magnetic properties for these groups of samples. The unoxidised massive flows are more intensely magnetised than either the oxidised massive flows or the oxidised pillow basalts. Similar to what has been reported from laboratory studies⁷, the natural low temperature oxidation of titanomagnetite to titanomagmaemite causes a decrease in intensity of remanence and saturation moment, and an increase in coercivity and Curie temperature. Weak field susceptibility also decreases with oxidation.

Low temperature oxidation is important in the control of the magnetic properties of submarine basalts, particularly in the fine grained pillow material. Evidence for hydrothermal alteration at moderate temperatures was absent from all four sites on the Nazca Plate. The presence of unoxidised titanomagnetite grains in the massive volcanic units of the 40-Myr-old site 321 and 15-Myr-old site 319 indicates that flow structure can be a more important factor in the alteration history than age alone.

We thank Professor E. E. Larson for a constructive review.

Evidence for a new aluminium phosphate phase from reaction rate of phosphate with aluminium hydroxide

THE reaction between phosphate and aluminium hydroxide is important in soil fertility and also in the management of systems whereby waste water is disposed directly on to the land. The retention of phosphate by a sandy topsoil during 50 yr of application of raw sewage water cannot be accounted for by adsorption on soil constituents alone¹. It was suggested that precipitation of the phosphate had probably taken place. Later investigations on this soil (Beek, personal communications) indicated the presence of an aluminium phosphate as the main fraction of phosphate retained. We report here results for the production of aluminium phosphate which may have a bearing on waste water management.

Most of the older research on the precipitation of aluminium phosphate involved systems using high phosphate concentrations and/or high temperature^{2–5}. The experiments reported here were done at 20.5 ± 0.1 °C with an initial phosphate concentration of $0.36 \text{ mmol dm}^{-3}$ at pH 5. X-ray amorphous aluminium hydroxide with a specific surface area (B.E.T.) of $226 \text{ m}^2 \text{ g}^{-1}$ was used⁶. The pH was kept constant (± 0.1) by the addition of HCl. From aliquots of the suspensions the phosphate concentration was measured after filtration through a Millipore (0.1 μm) filter.

Fig. 1 A semi log plot of the measured phosphate concentration as a function of reaction time for a suspension concentration of $0.2 \text{ g dm}^{-3} \text{ Al(OH)}_3$. For the period 1–40 d, the first order rate constant, $K_{1-40 \text{ d}}$ equals 0.0069 d^{-1} .

The results of the measurements are given in Figs 1 and 2. Figure 1 shows that, for the time period from ~1 to 40 d, the rate can be described by first order kinetics.

$$\ln \frac{c_0'}{c} = Kt \quad (1)$$

where $c_0' = c$ at about 1 d of shaking, K = rate constant d^{-1} , c = phosphate concentration. Similar observations have been reported⁷ for the reaction of phosphate with $\alpha \text{ Al}_2\text{O}_3$ and with kaolinite.

The value of K depends on the amount of specific surface area per litre and on the charge of the surface which is dependent on pH. Another way to express the measured data is in terms of the amount of phosphate removed from the solution per g Al(OH)_3 . This is shown in Fig. 2 using a double log plot.

Figure 2 shows two different straight lines. The first line (up to about 1 d) represents the fast adsorption on the surface of the

$\text{Al}(\text{OH})_3$, a short term reaction which has been shown previously⁸. After 1 d the reaction rate increases markedly compared with the first process, a phenomenon which remains hidden in Fig. 1. Such an increase in reaction rate could conceivably be caused by the initiation of the growth of a crystalline aluminium phosphate. This supposition was tested using electron microscopy, electron diffraction and X-ray diffraction. These techniques were applied after a reaction time of 62 d. Crystalline particles of a platy structure were visible, some of them

From the evidence given here it is not unlikely that the growth of an aluminium phosphate phase is the rate determining step after 1 d in this system. Similar experiments were done with $\alpha\text{-Al}_2\text{O}_3$ and with solutions containing different ions at pH 5 and 6. It is interesting to note that the intersection point of the two straight lines in Fig. 2 occurs at a reaction time of 4 d for the case of $\alpha\text{-Al}_2\text{O}_3$. The results of these experiments which are comparable with the ones given here will be published elsewhere.

Excess of atmospheric neon in pumice from the Islands of Lipari

LORD RAYLEIGH¹ reported an excess of neon (over argon) in pumice from the Lipari Islands. Dymond and Hogan² have reported excesses of neon in mid-oceanic tholeiitic basalts and have suggested that they indicate primordial neon. As the search for primordial gases in terrestrial rocks has an important bearing on our understanding of the formation and thermal history of the Earth, we decided to look at the isotopic composition of the neon in pumice from the Lipari Islands. We

collected fresh specimens from the largest quarry on the islands and extracted the included gases by crushing in a vacuum line and by stepwise heating. The five noble gases were measured in a mass spectrometer.

Large differences were observed in the noble gas contents in three samples (Table 1) A, B and C, indicating heterogeneity in the noble gas distribution, a feature that also seems to be common in basalts. In all of the samples significant excesses of neon were observed, the $^{20}\text{Ne}/^{36}\text{Ar}$ ratio reaching the value 15.8, as compared with the atmospheric value of 0.52. This excess neon has $^{20}\text{Ne}/^{22}\text{Ne}$ and $^{22}\text{Ne}/^{21}\text{Ne}$ values that are indistinguishable from the atmospheric ratios, in the limit of the given analytical errors (Table 1).

whether they are primordial or atmospheric. The mechanism by which the pumice takes up neon upon its formation needs further study (the fact that the helium is less enriched could be a result of subsequent diffusional losses).

Fig. 1 The isotopic composition of the excess neon in the Lipari pumice compared with known species of primordial neon in extraterrestrial sources (following ref. 3); a, neon A; b, neon B; c, neon C; d, solar wind; e, neon E; arrow, Lipari pumice and atmosphere.

The fact that the same type of neon is observed in crushing and stepwise heating experiments indicates that only one type of neon is present. Further, the observed isotopic composition deviates from any known species of primordial neon in extraterrestrial material (Fig. 1).

These data seem to indicate that the excess neon in pumice from the islands of Lipari is of atmospheric origin. Similar isotopic measurements in the mid-oceanic basalts might clarify

Long range transport of toxaphene insecticide in the atmosphere of the western North Atlantic

OVER the past ten years toxaphene has been used in the USA in larger quantities than any other insecticide, with an estimated consumption of 58 million pounds per year (ref. 1). In spite of this widespread use, the composition of toxaphene remains largely undetermined, and recent work indicates that the technical product contains nearly 200 polychlorinated camphenes². Because of the difficulties in analysing such a complex mixture, little is known about the dissipation of toxaphene in the environment. Residues in soils may persist for years, with volatilisation suggested as a major loss mechanism³. Toxaphene has been identified,

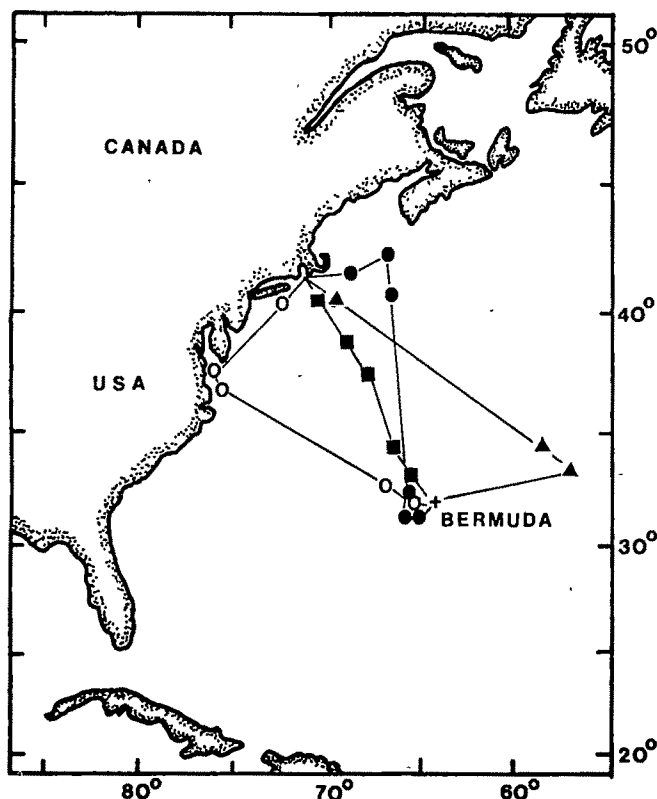

Fig. 1 Atmospheric samples collected from the RV Trident, 1973–74 (see Table 1 for cruise dates). ■, TR-137; ○, TR-145; ●, TR-152; ▲, TR-153.

however, in US air samples in only three locations⁴, all in southern agricultural areas, at levels of 16–2,520 ng m⁻³. The ability of high molecular weight chlorinated hydrocarbons to be transported long distances through the atmosphere has been well established within the past decade. Polychlorinated biphenyls (PCBs)^{5,6}, and the chlorinated pesticides DDT⁷⁻⁹, dieldrin^{7,8}, and chlordane⁹ have been identified in the air over the western North Atlantic. We now report that toxaphene is also carried through the atmosphere at least 1,200 km out to sea.

During 1973–74 we collected 36 air samples from a tower on the south shore of Bermuda and 20 from the bow of the RV Trident on cruises in the western North Atlantic (Fig. 1), and in the spring of 1975 we took six samples at Sapelo Island, Georgia—two on the island and four from the RV Kit Jones, 6–20 km from the coast. The collection system in Bermuda was controlled by wind direction, which enabled us to sample air blowing from a desired sector¹¹. Of the 36 Bermuda samples, 26 were taken only when the wind blew from inside a 90°E–240°SW selected sector (ISS). This air passed over hundreds of kilometres of open ocean and not over the island of Bermuda. Seven samples were collected when the wind blew from outside this sector (OSS) and thus over portions of the island, and the remainder were collected during periods of variable winds.

The samples were taken by drawing 200–3,000 m³ of air through a Gelman A glass fibre filter and then through plugs of polyurethane foam^{6,10}. In most cases we analysed only the foam plugs, since previous work indicated that other chlorinated hydrocarbons are poorly retained by glass fibre filters when large air volumes are sampled. We checked this for a few samples, and found that less than 5% of the total toxaphene was retained by the glass fibre filters, the bulk of the pesticide being found on the foam plugs.

Toxaphene was identified by electron capture gas chromatography on both 1.5% OV-17–1.95% QF-1 and 4%

SE-30–6% QF-1 columns after separation from PCB, DDT, and chlordane by silicic acid column chromatography. The 'toxaphene fraction' from the silicic acid column (3 g, 3.3% water), eluted with dichloromethane after eluting the PCB and DDT–chlordane fractions with petroleum ether, contained the components contributing 60–70% of the total toxaphene electron capture response before separation. Gas chromatograms of the sample extracts and a toxaphene standard contained a number of peaks reminiscent of a PCB pattern (Fig. 2a and b) which were unchanged by treatment of the sample or standard with a mixture of concentrated sulphuric and fuming nitric acids, a procedure which removes residues of DDT, dieldrin, and organophosphate pesticides^{12,13}. The presence of toxaphene was further confirmed by refluxing the sample extracts with alcoholic potassium hydroxide and comparing the resulting gas chromatograms with those of authentic dehydrochlorinated

toxaphene (Fig. 2c and d). Toxaphene was quantitated by comparing the sum of the peak heights in sample and standard chromatograms.

Atmospheric concentrations of toxaphene over the western North Atlantic are reported in Table 1. For several reasons we think that the majority of toxaphene in the air did not originate from Bermuda: (1) the Bermuda Department of Agriculture and Fisheries assured us that toxaphene has not been used on the island for the past 3–4 years; (2) the mean toxaphene concentration of Bermuda samples collected OSS (0.81 ± 0.45 ng m⁻³) (precision reported as s.d.m.) was little different from the mean of those taken when the wind blew ISS (0.72 ± 0.09 ng m⁻³); and (3), comparable levels were measured over the open

Fig. 2 Gas chromatographic identification of toxaphene in western North Atlantic air, 4% SE-30/6% QF-1 column. *a*, Bermuda air sample; *b*, toxaphene standard, 3 ng; *c*, Bermuda air sample, after dehydrochlorination; *d*, Toxaphene standard, 1.4 ng, after dehydrochlorination.

ocean, indicating that our Bermuda values were unlikely to be the result of local contamination.

Our mean levels of toxaphene in western North Atlantic air are about equal to or twice those of PCBs^{8,9}, and more than ten times higher than those of other pesticides so far reported in the marine atmosphere. These higher residues probably result from both the large scale use of toxaphene and its volatility. The mean toxaphene concentration (ng m^{-3}) in our 56 samples from Bermuda and RV Trident was 0.63, as against 0.024 for *p,p'*-DDT. We note that the ratio of these concentrations (26) is close to the ratio of the outdoor evaporation rates of the two pesticides (25) (ref. 3). A possible source of airborne toxaphene is the southern US cotton growing areas, where the bulk of this pesticide has been used in combination with DDT (up to 1973) or methyl parathion¹.

We thank the US Naval Underwater Sound Laboratory, Tudor Hill, Bermuda, for providing a site for the construc-

tion of the air sampling tower, and the University of Georgia Marine Institute, Sapelo Island, Georgia, for providing ship time on the RV Kit Jones. We are grateful to Paul DesLauriers and Ian Fletcher for their help in sample collection.

New interglacial site at Sugworth

A PRELIMINARY account is given of a richly fossiliferous interglacial deposit of Middle Pleistocene age at Sugworth, near Oxford, UK.

Excavations for the A34 Abingdon bypass during 1972-73 revealed four fossil channels cut into the Kimmeridge Clay (Figs 1 and 2). The tops of the channels lie at 92 m OD, 40 m above the present level of the River Thames, and seem to represent a former meandering river trending roughly from north to south. In one section near Sugworth Lane (OS ref.: SP 513007; Fig. 2) the channel fill, approximately 180-200 m wide and up to 5 m deep, included organically-rich silts and sands passing laterally into sands and gravels and upwards into about 0.5 m of yellow silty clay. Across the channel fill an unconformable layer, 1-2 m thick, of pebbly sandy clay could be followed along the cutting for 100 m or so beyond the channel. This latter deposit has been mapped by the UK Geological Survey (Sheet 236) as 'Plateau Gravel' and 'Unbedded Drift', the first designation identifying it with the Plateau Drift of the Oxford region which most workers have regarded as wholly or in part of glacial origin¹.

Pebble counts and heavy mineral analyses of the channel sediments, the overlying pebbly clay, and several samples of Plateau Drift from the Oxford region, were compared in an attempt to establish their mutual relationships. Quartz, quartzite and sandstone, derived ultimately from the Bunter Pebble Beds, presumably of the Midlands, are major constituents of all three. Flint, derived from the Chalk, possibly when the scarp extended further north than it does today, is common throughout, but limestone of both Kimmeridge and Oolitic lithologies is abundant only in the channel sediments. In contrast, the channel sands and the overlying pebbly clay resemble each other and the Kimmeridge Clay

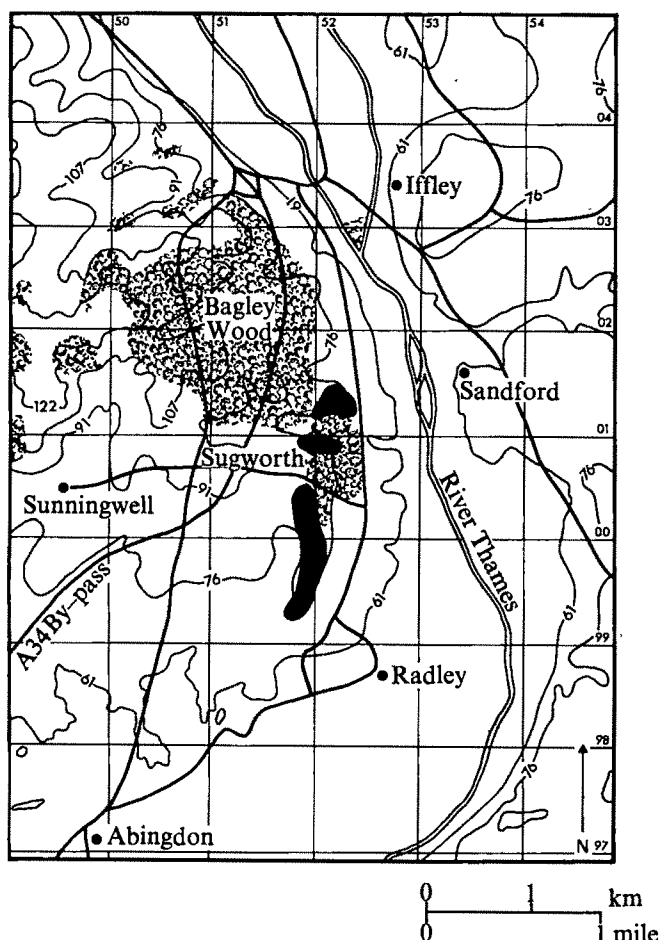

Fig. 1 Map showing location of Sugworth in relation to the Hanborough Terrace (black areas) and the modern River Thames.

in their zircon-dominated assemblage, whereas it has been shown that zircon is rare in the Plateau Drift².

The organic channel sediments are rich in molluscs, beetles and macroscopic plant remains, and vertebrates also occur. Unfortunately, well preserved pollen has not so far been recovered.

The macroscopic plant fossils represents aquatics (for example, *Callitriche* sp. and *Nuphar lutea*), plants characteristic of wet soil (for example, *Lycopus europaeus*, *Eupatorium cannabinum* and *Filipendula ulmaria*), Cyperaceae (sedges), open ground herbs (*Atriplex* sp., *Chenopodium* sp., *Rumex* sp., *Plantago major* and *Leontodon autumnalis*), forest trees (*Acer campestre*, *Alnus glutinosa*, *Carpinus betulus*, *Abies* sp. and *Picea* sp.) and shade tolerant herbs (for example, *Moehringia trinerva*). The logs collected from the deposit are mostly *Ulmus*, together with *Quercus* and a Rosaceae taxon, probably *Crataegus* (hawthorn).

The molluscs from the basal 3 m include many moving water/river species (for example, *Unio crassus*, *Ancylus fluviatilis*, *Valvata piscinalis*, *Bithynia* sp., *Pisidium amnicum* and *P. henslowanum*) reflecting conditions of deposition in a large river. Shells washed in from other habitats include species of reed swamp and fen (for example, *Succinea* spp., *Carychium minimum*, *Cochlicopa lubrica*, *Vertigo angustior* and *Hygromia hispida*) together with a 'slum' group indicative of the presence of small bodies of water, liable to dry up (*Sphaerium lacustre*, *Planorbis leucostoma* and *Pisidium obtusale*), snails of drier rather open terrestrial habitats (for example, *Vallonia costata*) and those favouring a denser forest cover (for example, *Azeca* cf. *menkeana* and *Discus rotundatus*).

Vertebrates include fishes (for example, *Esox lucius*), amphibians (*Rana* sp. and/or *Bufo* sp.) and small mammals (*Sorex* cf. *savini*, *Talpa* sp., *Clethrionomys glareolus*, *Mimomys savini*, *Microtus* sp. and *Apodemus* (sylvaticus group)). Remains of large mammals are few but include a tooth of the rhinoceros *Dicerorhinus etruscus*. The predominance of remains of woodland rodents *Clethrionomys* and *Apodemus* over those of the grassland vole *Microtus* contrasts with assemblages from West Runton³, where the reverse is true, and suggests that forest grew close to the river.

The extensive beetle fauna includes a number of species such as *Hypulus quercinus*, *Eremotes lignarius* and *Dryophthorus corticalis*, which live in deciduous woodland. The general picture, therefore, is of a large river flowing through fairly dense, mixed oak forest, probably with locally developed, herb dominated communities and marshy areas on the floodplain. The channel sediments seem to have accumulated on the inside of a meander.

The faunal and floral evidence strongly indicates a temperate climate and there is no doubt that the deposit is of interglacial age. Some of the plants (for example, *Najas minor*, *Abies* and *Trapa natans*) occur today in central or

* Cromerian records are from the type site at West Runton, Norfolk⁷.

† B. W. Sparks, personal communication.

southern Europe. The beetle fauna includes a substantial proportion of species no longer living in Britain but all found further south in Europe today. Examples of this group are *Oxytelus opacus*, *Pelochares versicolor* and *Valgus hemipterus*. There is thus no doubt that the interglacial experienced warmer summer temperatures than the south Midlands of the UK today.

The insect fauna cannot be compared with a definitive Cromerian assemblage as nothing of that age has yet been fully investigated. It is significant, however, that it bears no resemblance to Hoxnian faunas of the Midlands which have been closely studied (ref. 4, and Kenward, unpublished), but there is a marked resemblance to the Ipswichian fauna from Trafalgar Square, London. Nonetheless, a correlation of the Sugworth deposits with the Ipswichian is surely precluded on stratigraphical grounds and on consideration of other fauna and flora with a restricted distribution in time. The known stratigraphical ranges of certain of the Sugworth taxa in deposits of the last three British interglacials (Table 1) cumulatively point to a Cromerian age for the Sugworth channel deposits. More specifically, the abundance of *Carpinus* fruits and the remains of *Abies* and *Picea* suggests that the deposit belongs to zone CrIII. A radiocarbon assay gave an 'infinite' date (Birm 381).

The Sugworth deposit lies topographically well above the Hanborough Terrace (see Fig. 1) which has been ascribed both to the Hoxnian Interglacial and, more recently, to an early part of the Wolstonian⁵. It must, therefore, be at least as old as the Hoxnian and is more

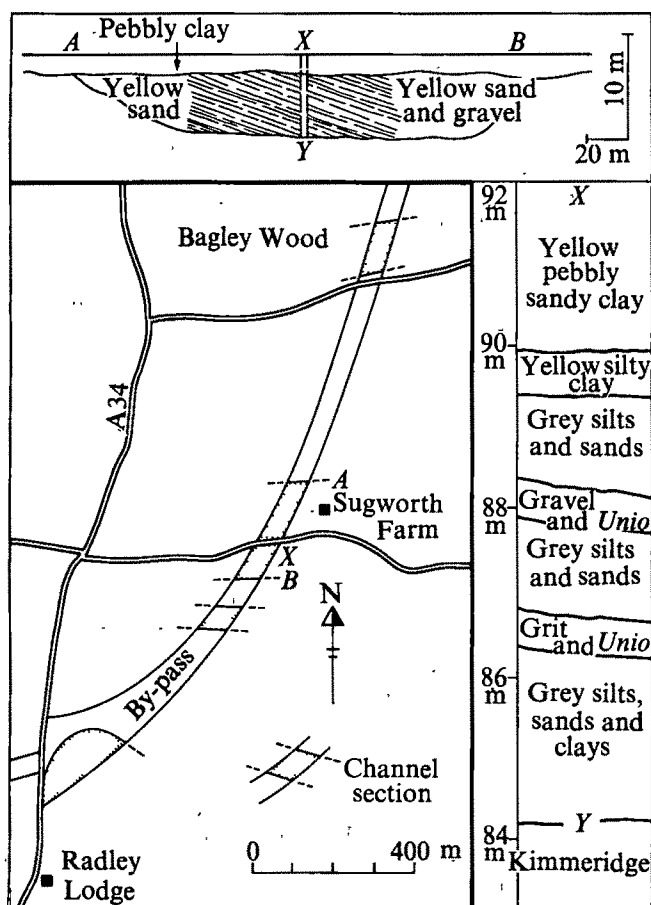

Fig. 2 Location of the channels: idealised section (A-B) of the channel (vertical exaggeration, $\times 5$) with fossiliferous deposits obliquely shaded; detailed stratigraphy, X-Y.

probably even older than that. The evidence that it is Cromerian has wide implications for the Pleistocene stratigraphy of the Oxford region⁸. Of the coarse constituents of the channel deposits, only the Bunter pebbles pose a serious problem since it is possible to suggest a local or near-local source for the other types. If the Bunter pebbles are derived from the Plateau Drift, then that deposit is pre-Cromerian and the pebbly clay which overlies the channel is not Plateau Drift, though it may be a solifluction deposit from it. Since no glacial deposits earlier than the Anglian stage (that is, post-Cromerian) have so far been reliably identified in Britain⁷, the whole question of the mode of deposition of the Plateau Drift, glacial or otherwise, would need clarification were a pre-Cromerian age accepted. If, on the other hand, the pebbly clay above the channel is considered to be Plateau Drift, then that deposit remains in the Anglian stage. In that case, however, a new problem arises: by what mechanism did the Bunter pebbles arrive at Sugworth if earlier ice-transport is ruled out? Possibly, since the channels seem to be part of a river system flowing roughly from the north (assuming that they are indeed relics of a very old river system greatly at variance with the modern pattern) the Bunter pebbles could have been transported from the NNW by fluvial processes. In any case, a minimum distance of transport of 100 km is demanded.

In a wider context Sugworth is important as the only known British open site of Cromerian age outside East Anglia.

We thank the Amey-Fairclough Consortium, the Department of Forestry, Oxford and Dr R. W. Hey for assistance.

Adverse effects of maternal alcohol consumption on pregnancy and foetal growth in rats

JONES *et al.* have recorded several combined aspects of dysmorphogenesis, severe physical growth retardation and mental deficiency in the human and named it "foetal alcoholic syndrome", suggesting the defects to be associated with offspring of chronically alcoholic mothers¹. Sandor and Amels² found that ethanol seemed to produce distinct teratological effects in Wistar rats and chick embryos when it was administered intravenously to the pregnant mother or the hen at critical periods in gestation.

In spite of the increasing influence of alcoholism in Western society and the trend toward increased concern for human prenatal health care, no systemic model—human or animal—has been designed to ascertain the adverse effects of maternal alcoholism on the outcome of pregnancy and the growth of the developing foetus. Adequate data in this field are lacking³. This study proposes a simple experimental model to elucidate some information in this area.

Thirty-seven inbred Sprague-Dawley female rats (each about 200 g; Bio-Breeding Laboratories, Ottawa, Canada) were randomly divided into two treatment and one control group, and housed individually in wire cages. For a 5-week period before mating, 13 females (group A) received ethanol in 30 g per 100 ml water as their only available fluid, and a balanced powdered diet (Table 1) *ad libitum*. After 1 month, blood samples were taken from the tails of 10 group A animals for the determination of blood alcohol levels according to the alcohol dehydrogenase method. The

Table 1 Composition of powdered diet (4.2 calorie g⁻¹) fed to all three groups of studied animals

Component	% (by weight)
Casein	20
Corn oil	10
Cornstarch	64
Alphacel	1
Mineral salts	3
Vitamin preparation	2

pair-fed group (B) received water *ad libitum* and were fed a diet isocaloric with that of the group A animals. The isocaloric diet was determined on the basis of the average daily caloric intake of group A animals, in the consumption of both the powdered diet and ethanol. The control group (C) received food and water *ad libitum*.

Food and fluid intake records were kept for all three groups. At mating, three females with one male of the same age, source and strain were placed in each standard plastic breeding cage overnight. All these groups of animals were allowed water during the nights on which they were mated. The presence of sperm cells in vaginal smears taken the following morning was taken as positive indication of pregnancy. Group A animals continued to receive alcohol and the intake of group B animals was regulated accordingly throughout the gestation period. All offspring were examined, weighed and counted on the day of birth.

Table 2 Copulation and delivery rates of alcohol-fed, pair-fed and control group females

Group	Number	Positive smears	Successful deliveries
A	12	10 (83%)	5 (50%)
B	13	11 (85%)	10 (91%)
C	11	8 (75%)	7 (88%)

A, Alcohol-treated; B, pair-fed to alcohol-treated; C, control.

Throughout the study period, the daily weight gain of group B females paralleled closely that of control females. Group A animals, after an initial sharp decline in weight with change in environment and start of ethanol administration, gained weight in a pattern similar to that of control and pair-fed females but the group mean weight remained at least 20 g below those of groups B and C (Fig. 1). The mean serum alcohol level of ten group A animals was 61 ± 23 mg %.

No significant difference was found among the three groups with respect to numbers showing positive indications

Fig. 1 Maternal daily weight changes during prenatal and gestational periods in three groups of studied animals. A, Alcohol-fed; B, pair-fed to group A; C, control.

of pregnancy; but whereas 88 and 91% of control and pair-fed females, respectively, which copulated, produced litters, only 50% of group A mothers known to have copulated, delivered litters (Table 2). The average litter size of alcohol-treated mothers (7.2) was significantly lower than the mean litter size of either pair-fed or control mothers in this study. The mean birth weight (4.58 g) of group A litters was also lower than that of litters of group B or C animals (Table 3, Fig. 1). Gestation period did not vary among the three groups; all litters delivered at 21 to 22 d *post coitum*.

In addition to small size, offspring of group A mothers exhibited microcephaly, cracked, dry, loose skin, reddened areas on the head and body, and a generally shrivelled appearance.

Table 3 Birth weights of progeny and litter size of alcohol-fed, pair-fed and control females

Group	Mean birth weight (g)	No. of animals per litter at birth

N, Total number of offspring; n, total number of litters; A, alcohol-treated; B, pair-fed to alcohol-treated; C, control.

Toews and Lee studied the effect of maternal dietary deprivation of rats on growth and development of progeny⁴, and found that there was no significant effect of nutritional deprivation on litter size, although the mean weight of the progeny was significantly decreased (5.89 g for the offspring of nutritionally restricted animals compared with 6.60 g for offspring of control animals). The difference between the means was 0.71 g. In the present study, the mean weight of progeny in control litters was 5.88 g, whereas that of alcohol-fed litters was 4.58 g. This striking difference of 1.30 g indicates the greater effect of maternal alcohol consumption, rather than dietary restriction, in controlling the size of progeny. Although mothers which were pair-fed to alcohol-ingesting mothers received a somewhat restricted intake of 60 calorie d⁻¹, when compared with *ad libitum* intake of control mothers at 68 calorie d⁻¹, the data show no significant difference between control and pair-fed groups with respect to any of the parameters studied.

Our results indicate that maternal consumption of alcohol before and during pregnancy markedly decreased the size and number of progeny produced. These effects do not seem to be calorie-dependent but rather to be direct effects of the ingestion of alcohol. The simple experimental model used here can readily be applied to other investigations of the adverse effects of maternal alcohol consumption on morphogenesis, foetal growth, postnatal growth and behavioural development of the offspring.

Alcohol prolongs time course of glare recovery

SUDDEN changes in environmental light levels require the eye to readjust to achieve the same sensitivity to target contrast at the new level, a process which takes many seconds or minutes when the new environment is considerably dimmer than the previous level. During this recovery time, the eye is relatively blind to fine detail. We show here that relatively low doses of alcohol significantly prolong recovery times following bright light exposure; these changes can be seen for several hours following alcohol ingestion.

When the integrity of the retina is disturbed by drugs or disease, the adaptation process is retarded and the recovery of contrast sensitivity is prolonged^{1,2}. Halothane anaesthesia has been shown to markedly prolong the retinal dark adaptation process³. Alcohol, a commonly used drug, is also known to have a direct effect on the human retina; the b wave^{4,5} and the c wave⁶ of the dark-adapted electroretinogram are altered by alcohol at levels commonly encountered in social drinking.

Nine young male subjects (aged from 20 to 28) participated in a replicated 3 × 3 crossover experiment which was run double blind. Two alcohol doses (0.5 and 1.0 ml per kg body weight) and a placebo were used. Alcohol in the form of 95% ethanol was diluted with fruit juice so that the total volume (ml) was three times the subject's body weight (kg). The drink was consumed through a straw from a lidded paper cup which also contained two ice cubes. To minimise olfactory cues to the presence of alcohol, 2 drops each of ethanol and eucalyptus oil were placed on the lid of the cup. Twenty minutes were allowed for the consumption of the drink. Blood alcohol level (BAL) was estimated before drinking and at intervals after drinking using the Intoxilyser (Omicron Systems, Palo Alto) which

Fig. 1 Glare and test field configuration: Subjects preadapted for at least 5 min to the low photopic luminance levels of the laboratory. Aided by four thin diagonally oriented reference lines, the subject fixated the centre of a 20° circular adapting field of 5.6×10^4 cd m⁻² with the right eye. Immediately following a 10-s exposure to the high intensity adapting field, the subject fixated the centre of the stimulus configuration where a 5 arc min test spot was intermittently presented (125-ms flashes at 4 Hz) on a 22.6 cd m⁻² background. The contrast of the 5 arc min test spot was controlled by the subject. When he had recovered contrast sensitivity and detected the target, he operated a switch to reduce the target contrast a further fixed step below his threshold. The contrast levels of the test spot, 5.34, 2.00, 1.45, 0.99 and 0.64, were chosen to give approximately equal time periods between each recovery point. Four sets of measurements were taken with 5 min allowed between sets for complete recovery from the adapting luminance level. Photographs of the left eye were taken on five subjects 5 s before and 5 s into the exposure of the high intensity adapting stimulus for the first trial of each test period. Measurements of pupil size were made from the projected negatives.

Fig. 2 The time course of adaptation for placebo and alcohol 90 min after drinking. 1.0 ml per kg body weight of 95% ethanol (○); 0.5 ml per kg body weight of 95% ethanol (△); placebo (□). The dose relationship for the alcohol doses is evident in the displacement of the two alcohol treatment curves. The insensitivity of the measure to placebo treatment is also shown here: the mean pre-drink recovery times collapsed across test days (×) fall on the curve generated by the placebo recovery times.

estimates BAL using infrared spectroscopy of a breath sample.

Details of the stimulus presentation are shown in Fig. 1. Subjects practised the task to achieve stable performance before participation in the experimental sessions. On a given experimental day, they were tested before drinking and 30, 90, 180, 270, and 360 min after drinking. At each of these test times, blood alcohol levels and subjective 'high' ratings were ascertained by a second experimenter. Subjects rated their 'high' on a scale of zero to 100, where zero was sober and 100 was as high as a subject had ever been on alcohol.

The time course of adaptation following a 10-s exposure to a uniform bright field is significantly retarded after alcohol

Fig. 3 Group mean recovery time (s) as a function of time after drinking. These functions describe the time course of the alcohol induced light adaptation changes for the five contrast levels and each drug condition. The shaded area indicates the time of alcohol ingestion. Symbols as in Fig. 2.

ingestion. Figure 2 shows the group recovery time to test spots of different contrast for placebo, 0.5, and 1.0 ml of 95% ethanol per kg body weight doses 90 min after drinking. The group recovery times for the low alcohol (0.5 ml kg⁻¹) and high alcohol (1.0 ml kg⁻¹) doses are all increased significantly ($P < 0.02$ Walsh test) when compared with the corresponding pre-drink values. For the 1.0 ml kg⁻¹ alcohol dose, group mean recovery times are delayed by between 30 and 50% compared with the corresponding placebo values.

The alcohol induced increase in recovery times is apparent in the first measurement period (30 min), peaks at the 1–2 h point, and thereafter declines to reach pre-drink values approximately 6 h after drinking (Fig. 3). There is a significant systematic increase ($P < 0.01$, Friedman two-way analysis of variance) in glare recovery time at all five contrast levels for the high dose of alcohol (1.0 ml kg⁻¹); for the low dose of alcohol (0.5 ml kg⁻¹) the shift is statistically significant ($P < 0.05$) for two contrast conditions (2.00, 0.99). Recovery times at all contrasts remain elevated 3 h after drinking.

The alcohol induced increases in recovery times are dose related. The dose relationship is clearly evident 90 min after drinking (Fig. 2). Furthermore, it is evident from Fig. 3 that a dose relationship exists for at least 3 h after drinking when the mean BALs are quite low (0.01 and 0.05 g% for the 0.5 and 1.0 ml kg⁻¹ doses, respectively).

Relatively low doses of alcohol produce significant dose-related delays in the recovery of contrast sensitivity following exposure to intense light levels. The relationship between BALs and the increase in recovery times is illustrated in Fig. 4. Both the mechanisms of the alcohol induced change in the adaptation process and the consequences for a wide range of practical tasks deserve attention.

How does alcohol ingestion produce the increased recovery times? A number of preretinal factors could be involved, including pupil size changes, pupil response to the adapting stimulus, accommodative error, and accuracy of eye fixation.

Fig. 4 Mean recovery time to targets of five contrasts as a function of blood alcohol level. The range of blood alcohol levels was divided into five equal intervals and the corresponding glare recovery times were averaged within these intervals. The number of measures contributing to each point is indicated along the abscissa. Contrast levels: 5.34 (□), 2.00 (△), 1.45 (○), 0.99 (◆), and 0.64 (▽).

Fig. 5 Recovery time (s) to five different contrasts as a function of time after alcohol (1.0 ml kg⁻¹); subject J.W. Contrast levels: 5.34 (□), 2.00 (△), 1.45 (○), 0.99 (◆), and 0.64 (▽). Shown below is pupil diameter (mm) for this subject before exposure to the glare field (■) and during exposure to the glare field (●) as a function of time after alcohol.

Alcohol induced changes in pupil size could be expected to influence the recovery time to fixed contrast targets. Pupil size showed no consistent variations, however, either with time after drinking or across drug treatments. Figure 5 shows the results for a subject whose glare recovery times were markedly altered by alcohol at all contrast levels. The pupil sizes before and during glare exposure, 90 min after drinking, are no different from their pre-drink counterparts; at this same time there is an average of 54% increase in glare recovery time for the subject. Inaccuracies of accommodation to the test target or inexact foveal fixation could produce longer recovery times. It is unlikely, however, that either of these factors was significant in these experiments. Perhaps the most important evidence for this statement is that visual acuity was unaltered by identical alcohol doses in another experiment on 10 young adult males (Adams *et al.*, unpublished).

Alcohol has a direct effect on the human retina⁴⁻⁶. Further, Raskin *et al.* have shown that alcohol slows dark adaptation and the resynthesis of photopigment in albino rats; their evidence suggests that this is due to the inhibition of a catalyst thought to be required for the oxidative resynthesis of retinaldehyde from retinol⁷. Although some of the evidence is indirect, we feel that preretinal factors and central mechanisms, which have little or no role in light adaptation⁸, are not significantly involved in the alcohol induced slowing of adaptation in our experiments. The results of Raskin *et al.* raise the interesting possibility that alcohol may be inhibiting the resynthesis of photopigment, an hypothesis that needs to be tested by measuring cone pigment kinetics.

The increased recovery time produced by alcohol intoxication must be viewed as critical from a practical point of view,

regardless of the mechanism. The period of recovery is a period of relative blindness for the individual and, as such, is potentially hazardous. Soon after sunrise and just before sunset the sky may act as an extended glare source for the automobile driver. The luminance levels in these conditions may be as high as those experienced by the subjects in our experiment⁹. In certain circumstances a driver will intermittently view the bright sky or be subjected briefly to high luminance glare from light scattered by the windshield. Following glare, important features of the driving environment must be seen against average background levels similar to those which we used. The possible consequences of an additional 30–50% delay in seeing critical detail in such circumstances are obvious.

We have demonstrated alcohol induced delays in glare recovery which we believe to be occurring at the retinal level. These delays have been demonstrated at surprisingly low BALs (approximately one cocktail on an empty stomach) and are dose related. The luminance parameters of the test are similar to luminance levels sometimes encountered in practice.

Macrophage proliferation induced *in vitro* by a lymphocyte factor

MACROPHAGE proliferation occurs *in vivo* as a component of the inflammatory response¹ and particularly intense proliferation is characteristic of the delayed hypersensitivity reaction to infection with facultative intracellular pathogens^{2–4}. The thymus-derived (T) lymphocyte is considered responsible for the expansion of the reticuloendothelial system in this type of infection⁵. Although the mechanisms by which lymphocytes induce macrophage proliferation and activation remain unclear, a number of lymphocyte-produced soluble mediators which influence the functions of macrophages have been described, including a biochemically distinct migration inhibitory factor (MIF) and chemotactic factor (MCF)⁶. The speculation that a lymphocyte-produced mitogenic factor may be responsible for the induction and maintenance of proliferation of macrophages prompted the present experiments.

There is evidence that macrophages proliferate *in vitro* in conditioned media or in the presence of a fibroblast-derived growth factor⁷ and two recent reports^{8,9} indicate that inflammatory exudates contain a factor which induces *in vitro* macrophage replication. Here we confirm our preliminary work¹⁰ in demonstrating that guinea pig lymph node lymphocytes in conditions shown to produce intense delayed hypersensitivity produce a soluble factor which induces guinea pig macrophages to proliferate *in vitro*.

Fig. 1 Sephadex column chromatography of lymphocyte supernatants. P and R supernatants were dialysed, lyophilised and subjected to Sephadex G-100 (superfine) column chromatography as described¹². Fractions were pooled and assayed for MIF activity on peritoneal macrophages at concentrations equivalent to the undiluted supernatants. MIF activity is expressed as percentage migration inhibition ([P/R] × 100) and depicted as columns. Markers for molecular weight estimation are depicted as curves. Molecular weights are given in parentheses.

Soluble mediators were prepared as previously described by us for the generation of MIF-rich supernatants¹¹. Briefly, Hartley guinea pigs were immunised with bovine gamma globulin (BGG) in Freund's complete adjuvant. Between days 14 and 17 regional lymph nodes were harvested and the cells collected and incubated for 24 h at a concentration of 15×10^6 per ml Eagle's MEM without serum, with and without BGG (1 mg ml^{-1}). After incubation, supernatants were collected and antigen was added to control supernatants. In these experiments, supernatants preincubated with antigen (P) were compared with controls reconstituted with antigen (R). Alveolar and oil-induced peritoneal macrophages from non-immunised animals were used in the capillary tube migration inhibition assay as described¹¹. Supernatants having potent MIF activity at a 1:2 dilution on the peritoneal macrophage (migration inhibition of 60–80%, that is, [P migration/R migration] × 100) were used in these experiments.

Peritoneal exudate cells and alveolar macrophages were incubated in glass tubes, Lab-Tech chambers or Falcon microculture plates for 30 min at 37°C to allow for the formation of monolayers. Non-adherent cells were removed by decanting followed by three washes in Hanks' balanced salt solution. Monolayers (>98% macrophages) were incubated for varying times in medium containing 20% foetal calf serum, 1% *L*-glutamine, and antibiotics. The incorporation of $0.5 \mu\text{Ci}$ of ^3H -thymidine (20 Ci mmol^{-1}) during

Table 1 DNA synthesis in macrophage monolayers

	Lymphocyte-produced mediator-rich supernatant dilutions	
	1:4	1:2
Alveolar macrophage	3.0 ± 0.3 (9)	4.2 ± 0.4 (12)
Peritoneal macrophage	2.8 ± 0.2 (33)	4.9 ± 0.4 (12)

Because of considerable variation in the background thymidine incorporation between alveolar and peritoneal macrophages and between one animal and another, the thymidine incorporation data for macrophage monolayers incubated for 5 d are expressed as the ratios (P supernatant/R supernatant) \pm s.e.m. of the ratios (number of samples). Mean c.p.m. thymidine incorporation for R supernatants were 7,300 c.p.m. for alveolar macrophages and 3,000 for peritoneal macrophages.

a terminal 24-h pulse was assayed. The tube cultures were processed as described¹². The microculture plates were twice freeze-thawed at -70°C to ensure release of the cells from the monolayer then processed by a multiple automatic sample harvester (MASH, Hiller), followed by liquid scintillation spectrometry.

Monolayers of macrophages incubated in MIF rich supernatants showed significant increases of thymidine incorporation peaking on the average at 5 d of culture. Table 1 shows the results of five experiments in which peritoneal and alveolar macrophages were incubated for 5 d in the presence of 1:2 and 1:4 dilution of P and R supernatants. Negligible decreases in thymidine incorporation were observed with R supernatants compared with media controls. The P supernatants consistently increased thymidine incorporation in both alveolar and peritoneal macrophages. The ratios of stimulation are significant ($P < 0.001$).

Table 2 DNA synthesis and content of macrophage cultures

	48 h		120 h	
	Thymidine incorporation	DNA content	Thymidine incorporation	DNA content
P fraction III	2,839	17.0	20,207	24.8
R fraction III	3,124	17.0	1,381	14.4
Medium control	8,430	18.2	668	16.8

Thymidine incorporation was assayed in microculture in which 1×10^5 peritoneal macrophages were allowed to attach for 30 min at 37°C . Monolayers were washed thrice and incubated for 48 or 120 h. Cultures were terminated with a 24 h ^3H -thymidine pulse (0.5 μCi) and assayed for thymidine incorporation by MASH and liquid scintillation spectrometry. DNA content was assayed in parallel using tube culture in which 5×10^5 macrophages were used for monolayer formation. DNA content of the cultures was measured by the method of Burton¹⁴. Data are expressed as mean c.p.m. or μg of DNA for triplicate determinations in a single experiment.

The crude supernatants contained antigen and possibly small amounts of antigen-antibody complex¹⁵, and since antigen-antibody complexes have been shown to induce macrophage proliferation¹⁶, we fractionated the supernatants on Sephadex G-100 and found that the major portion of the migration inhibitory activity eluted from the column in fractions of estimated molecular weight range of 35–60,000 (fraction III). Similarly, most of the mitogenic activity eluted in this fraction (Fig. 1). Figure 2 shows a time course of the effects of crude supernatants (1:2 dilution) and Sephadex fractions III run at a concentration corresponding to 1:2 and 1:4 dilution of the original supernatants. The increased mitogenic ratio of the supernatants observed in Fig. 2 compared with those given in Table 1 resulted from improving of the culture conditions, particularly a decrease of concentration of CO_2 from 5% to 1%. We have also observed mitogenic activity in fractions eluting before ovalbumin included in fraction II. These results suggest that the mitogenic factor and MIF may represent the same factor; however, we have found that by performing extensive vacuum dialysis of the supernatants before column chromatography (30 h resulting in a 40-fold concentration), we could deplete MIF activity to $< 20\%$ migration inhibition without significantly diminishing the activity of the mitogenic factor. This observation indicates that the mitogenic factor is distinct from MIF.

Table 2 compares the effects of Sephadex P and R fractions III run at a concentration equivalent to an undiluted supernatant and a medium control on thymidine incorporation and DNA content at 2 and 5 d of culture and demonstrates that the mitogenic factor (P fraction III) increases both the thymidine incorporation and DNA content between 48 and 72 h of culture in contrast to the R and medium controls. Microscopic analysis of monolayer cultures during the period of incubation indicated that, compared with R Sephadex fractions, monolayers exposed

Fig. 2 Time course of mitogenic factor action on macrophage monolayers. P and R supernatants diluted 1:2 were assayed for mitogenic activity on peritoneal macrophage monolayers over 5 d of culture (-----). Comparable supernatants were fractionated on Sephadex G-100 and pooled fractions III (see Fig. 1) were assayed for mitogenic activity at concentrations corresponding to dilutions of the original supernatants of 1:4 and 1:2 (———). Mitogenic activity was determined by thymidine incorporation. The data are expressed as the ratio of P/R thymidine incorporation.

to P fractions containing the mitogenic factor without MIF activity showed no gross differences in the number of adherent cells at plating and during the first 24 h of incubation and marked increases in the number of cells in association with the peak of thymidine incorporation. In an experiment in which the peak thymidine incorporation occurred at 96 h, mean cell counts for monolayers incubated with P fraction III and R fraction III were 47 and 18 cells per high powered field respectively and autoradiographic analyses of cells incorporating ^3H -thymidine were 22.1% and 9.8% labelled cells respectively. The increase in the number of labelled cells having the morphology of macrophages and containing vacuoles filled with oil used to induce the exudate indicate that macrophages were the cells proliferating.

These experiments indicate that lymphocytes in immunological conditions designed to produce intense delayed hypersensitivity produce on re-exposure to antigen *in vitro* a soluble factor which induces the proliferation of macrophages in monolayer cultures. Column chromatographic purification of this factor indicates that this factor elutes with an estimated molecular weight comparable with migration inhibitory factor. Vacuum dialysis before column chromatography indicates that the two factors are different. The factor is also distinct from antigen-antibody complexes, a recognised mitogenic influence on macrophages. On the basis of molecular weight estimation, the factor would seem to be distinct from a lymphocyte produced factor called blastogenic factor (molecular weight 20,000) which is mitogenic for lymphocytes^{15,16} and from a fibroblast-produced factor (molecular weight $> 100,000$) which is mitogenic for peritoneal macrophages⁷. The relationship of this factor to that which induces proliferation in uncharacterised peripheral blood cells remains to be determined. On the basis of comparisons of estimated molecular weight^{17,18}, we estimate that the factor is similar to lymphocyte-produced colony stimulating factor (CSF) which acts on macrophage precursors; CSF has, however, been shown to stimulate colony formation in peritoneal exudate cells only after a delay of 10–14 d and then only in a small fraction of the cells (5%)^{19,20}. To our knowledge, this repre-

sents the first demonstration of lymphocyte-produced macrophage mitogenic factor (MMF) acting on mature macrophages.

The experimental protocol used to elicit MMF offers strong presumptive evidence for its production by T lymphocytes; but whether other cells, for example B lymphocytes, also produce it remains to be determined. Its selectivity of action on target cells remains to be established as well. The biological relevance of MMF seems to be as a participant in the expansion of the expression of the efferent limb of cellular immune response and perhaps in the process of macrophage activation.

DNA present in multilayer rosette formed by lymphocytes stimulated with phytohaemagglutinin

ROGERS *et al.*¹ have reported that human lymphocytes of peripheral blood cultured in the presence of phytohaemagglutinin (PHA) undergo blast formation and synthesise DNA. This newly synthesised DNA which is excreted into the medium is reported to have a high molecular weight. The release of DNA by the cells is selective, as experiments with ¹⁴C-uridine indicated that RNA was not lost into the culture medium. The excretion of DNA by lymphocytes has also been noted by Olsen and Harris². Sarma and Rutman³ also found that PHA-stimulated lymphocytes incorporated labelled thymidine into small fragments that were then converted to high molecular weight material. Subsequently, the labelled thymidine reappeared in light fragments that were then released into the medium in an acid-precipitable form. It has also been reported that the human lymphocytes of peripheral blood are able to bind to sheep red blood cells (SRBC) in a rosette-forming cell⁴ when incubated together in stringent temperature conditions. In view of these findings the release of DNA synthesised by lymphocytes has been studied in connection with rosette formation.

Autoradiographs from the dry (labelled lymphocytes) and

Fig. 1 Autoradiographs of dry smears of human peripheral blood lymphocytes cultured for 48 h in the presence of PHA. Human peripheral blood lymphocytes were obtained from heparinised blood. Culture techniques were based on those described by Moorhead *et al.*⁵ and Hungerford⁶. PHA (reagent grade, Wellcome, UK, reconstituted) was used at a concentration of 0.1 ml per 10 ml culture medium. Cultures were maintained at 37 °C for 48 h. At 41 h, 5 μ Ci methyl-³H-thymidine (5 Ci mmol⁻¹) was added and after 7 h of labelling cells were collected, washed and resuspended in Hanks' balanced solution to a concentration of 1×10^6 ml⁻¹. This suspension, which contained more than 70% lymphoid cells, was split into two. One half was treated according to Moorhead *et al.*⁵ and Hungerford⁶. (Fixing with a mixture of methanol-acetic acid (3:1 v/v) and dry smears of the labelled lymphocytes were prepared. The slides were washed once with 5% Cl₃CCOOH, once with methanol and allowed to dry. The other half of the cultured lymphocytes was mixed with an equal volume of a 0.5% suspension of SRBC and after appropriate incubation (room temperature for 1 h) multilayer rosettes were formed spontaneously. These rosettes remain intact if they were reincubated at 37 °C for 60 min. A multilayer rosette was defined as a lymphocyte surrounded by at least 30 or more SRBC. From these rosettes thin smears were prepared. We used two kinds of control: one with lymphocytes without incubation⁴ and one with lymphocytes incubated for 48 h without PHA before rosetting. The percentage of rosette formation was the same for both, unless they were incubated for 60 min in an ice bath. Furthermore, the rosettes so formed contained only 5-10 SRBC. This observation is in agreement with the findings of Lay and Mendes⁴. The proportion of lymphocytes binding SRBC was found to be 10-15%, whereas Lay and Mendes⁴ have reported 20-40% and Bach *et al.*^{7,8} 0.4-2.6%. Cells were overlaid with a photographic emulsion (Kodak NTB2) and allowed to set for 3 d; after fixation they were counterstained with Giemsa.

the thin smears (multilayer rosettes) were prepared (for details, see Figs 1 and 2). Figure 1 shows that heavily labelled lymphocytes are present after a 48 h culture period. Up to 80% of the cells become blast-like in appearance and contain ³H-thymidine. Figure 2 shows the formation of multilayer rosettes as a result of incubating SRBC with ³H-labelled lymphocytes. Almost 70% of the lymphocytes formed rosettes, and the striking fact is the almost complete transfer of label from those lymphocytes to the SRBC (Fig. 2). Using human and rabbit erythrocytes instead of SRBC, no rosettes were formed at all, indicating that rosette formation does not depend on the presence of residual PHA on the surface of the blast.

To confirm that intracellular ³H-thymidine was in DNA the labelled cells were collected, taken up in a solution of sodium dodecyl sulphate (1.5%) in 0.01 M Tris buffer, pH 7.4, with 0.01 M EDTA, treated with NaOH at a final concentration of 0.3 M, precipitated with Cl₃CCOOH at a final concentration of 5% and collected on Millipore filters. These were washed twice with 5% Cl₃CCOOH, once with methanol, dried and counted in a scintillation counter. Acid-precipitable ³H-thymidine was determined. Furthermore, the nature of the label observed in SRBC after rosette formation was determined as follows. After culture

Fig. 2 An equal volume of lymphocytes ($1 \times 10^6 \text{ ml}^{-1}$) and 0.5% suspension of SRBC were mixed. The tubes containing the mixture were incubated at 37°C for 5 min, centrifuged for 5 min at $200g$, left at room temperature for 60 min, gently rocked to resuspend the cells in the pellet and thin smears were prepared. Autoradiographs were prepared as described in Fig. 1.

for 48 h duplicate tubes of labelled cultured lymphocytes were collected. On one set acid-precipitable ^3H -thymidine (c.p.m.) was determined as mentioned above; on the other set the cells were incubated with SRBC and rosettes were formed which were centrifuged at $500g$ for 10 min (supernatant I). The cell pellet was dissolved in distilled water and centrifuged at $5,000g$ for 10 min (supernatant II). In the cell pellet as well as in the two supernatants, acid-precipitable radioactivity was determined. That found in the labelled lymphocytes (see above) was identical to that in the cell pellet. The two supernatants contain almost zero acid-precipitable ^3H -thymidine radioactivity, indicating that acid-precipitable material is not present in the haemolysate, but bound to the erythrocyte stromata.

Human lymphocytes which had not incorporated ^3H -thymidine into their DNA, do not bind SRBC, although the thin smears were thoroughly scanned. This could mean that these cells have not been stimulated by PHA and are therefore unable to form rosettes. Furthermore, we have noted that PHA-stimulated lymphocytes lose their ability to form rosettes when fixed in a tube with a mixture of methanol-acetic acid (3:1 v/v). In this case lymphocytes were cultured as described previously, fixed in the tube and washed thoroughly in Hank's balanced solution. No rosettes were observed when we used lymphocytes so treated, indicating that cells must be viable to form rosettes.

Lymphocytes undergoing spontaneous transformation excrete DNA in a manner similar to lymphocytes stimulated with PHA and it is likely that this phenomenon is an intrinsic property of the lymphocyte rather than a special function induced by PHA. The observed presence of labelled DNA in the SRBC may reflect the transfer of ^3H -DNA between lymphocytes and SRBC. Although the explanation for the appearance of DNA in SRBC is obscure, a number of possibilities may be considered. Rosette formation is an interaction between a lymphoid cell and a heterologous erythrocyte which, although having some degree of specificity, is probably not immunological in nature. It would be difficult to admit that such a high proportion of peripheral blood lymphocytes (60–80%) have anti-SRBC antibodies on their membranes.

On the other hand the fact that the multilayer rosettes remained intact even at 37°C for 1 h or more is in agreement with the findings of Bach *et al.*^{7,8} for cluster formation between erythrocytes and lymphoid cells from immunised animals. A tentative hypothesis is to consider this phenomenon as a direct cell–cell interaction, which would depend

on the close apposition of large areas of the surfaces of the two cells in a manner impossible to achieve unless both cells were intact and possibly viable⁹. Finally, studies with a long term lymphocyte cell line¹⁰ have shown that about 0.5% of this DNA is associated with the cytoplasmic membrane. Whether these species of DNA are related to the DNA appearing in the SRBC is not known. Further studies on the functional significance of the findings reported here are now in progress.

We thank Professor F. Fessas for reading the manuscript and for discussion.

Are contact hypersensitivity cells cytotoxic?

THYMUS-DERIVED lymphocytes (T cells), which participate in many regulatory and effector functions of the immune system, are divided into distinct subpopulations. Thus, T cells causing cell-mediated cytotoxicity can be distinguished from those cooperating with bone marrow-derived lymphocytes (B cells) in the humoral response^{1–3}. Cytotoxic T cells also seem to be distinct from the cells responsible for the mixed lymphocyte and graft versus host reactions^{4,5}. Furthermore, T-cell subpopulations can interact with each other to augment various cell-mediated immune responses^{6–8}. We have investigated whether the T cells causing contact sensitivity belong to a different subset from those causing cell-mediated cytotoxicity. Our studies were based on two observations: first, that in mice contact sensitivity to the trinitrophenyl group (TNP) can be transferred adoptively by spleen or lymph node cells of sensitised animals; and, second, that cytotoxic T cells able to lyse TNP-coupled target cells can be induced *in vitro*^{11–13}. We have found that contact sensitivity cells fail to display cytotoxicity, while cytotoxic cells fail to transfer contact sensitivity. From this we conclude that these two functions are performed by distinct T cell subpopulations.

To induce contact sensitivity to TNP, C57BL/6 mice were sensitised twice by applying 0.1 ml 5% picryl chloride in ethanol to the clipped abdominal skin¹⁴. Five days later their ears were painted with 1% picryl chloride in olive oil and the increase in ear thickness determined after 24 h. Table 1 shows considerable ear swelling in mice sensitised twice, indicating significant contact sensitivity to TNP. After measurement the mice were killed and the draining lymph nodes (axillary and inguinal) were removed, minced, washed and suspended in RPMI-1640 (Microbiological Associates) containing 10% foetal calf serum. Aliquots of 5×10^7 cells were injected into normal C57BL/6 recipient mice, which were challenged immediately with 1% picryl chloride in olive oil applied to the ears. The lymph node cells from these sensitised mice transferred strong contact sensitivity, while the lymph node cells from normal mice did not.

Table 1 Transfer of contact sensitivity to TNP by lymph node cells and their inability to lyse TNP-coupled target cells

Contact sensitivity		Increment of ear thickness at 24 h in 10^{-3} cm \pm s.e.	
Test animals			
Donors: normal mice		7.0 \pm 0.8	
mice sensitised on day -6 and day -11		29.9 \pm 1.7	
Recipients: normal mice		5.0 \pm 0.2	
injected with 5×10^7 normal lymph node cells		6.1 \pm 1.5	
injected with 5×10^7 TNP-immune lymph node cells		15.8 \pm 1.1	
Cytotoxicity		% Cytotoxicity \pm s.e.	
Source of cells	Target cells	4 h	8 h
C57 B16 spleen sensitised to TNP-BALB/c (<i>in vitro</i>)	EL4	0	1.7 \pm 1.6
C57 B16 spleen sensitised to TNP-BALB/c (<i>in vitro</i>)	TNP-EL4	20.4 \pm 1.6	39.5 \pm 3.3
C57 B16 lymph node cells from TNP-C1 sensitised donor	EL4	0	0.3 \pm 0.2
C57 B16 lymph node cells from TNP-C1 sensitised donor	TNP-EL4	0	3.5 \pm 2.7

Donor mice: C57BL/6 mice were sensitised on days -12 and -6 with 100 μ l 5% picryl chloride and challenged on day -1 with 1% picryl chloride on both ears. Ear swelling was determined after 24 h. The mean increments in 10^{-3} cm \pm s.e. are given. Draining lymph nodes were removed and assayed for cell-mediated cytotoxicity at an attacker to target cell ratio of 100:1 on normal and TNP-coupled EL4 target cells¹². As a control, cytotoxic cells able to lyse TNP-EL4 targets were induced *in vitro* by culturing 10^7 C57BL/6 spleen cells with 5×10^4 TNP-coupled BALB/c spleen cells per ml (ref. 12). Spontaneous ^{51}Cr release was 3.2% h^{-1} for EL4 and 3.4% h^{-1} for TNP-EL4 targets. Recipient mice: 5×10^7 lymph node cells from normal and sensitised donors were injected into groups of five normal mice, which were challenged with 1% picryl chloride on their ears, to demonstrate their capacity to transfer contact sensitivity.

Percentage cytotoxicity calculated as:

$$\frac{(\text{experimental } ^{51}\text{Cr release} - \text{spontaneous } ^{51}\text{Cr release})}{(\text{maximal } ^{51}\text{Cr release} - \text{spontaneous } ^{51}\text{Cr release})} \times 100$$

The same lymph node cell preparation was tested for cytotoxicity toward normal or TNP-coupled syngeneic EL4 lymphoma target cells. At an attacker to target cell ratio of 100:1 and within 8 h these lymph node cells were cytotoxic neither to EL4 cells nor to TNP-EL4 cells. By contrast, C57BL/6 spleen cells sensitised *in vitro* to TNP-coupled BALB/c spleen cells¹² killed TNP-EL4 very efficiently, but not EL4, demonstrating that the TNP-EL4 were suitable targets for cytotoxicity. The failure of sensitised lymph node cells to lyse TNP-EL4 cells could have one of three explanations: (1) cells cytotoxic to hapten-coupled target cells are not present in the population responsible for the specific transfer of contact sensitivity to TNP; (2) cytotoxic cells are present in the sensitised population but are inactive (for example, because of suppression); or (3) cytotoxic cells are present but their activity cannot be detected because the assay is not sufficiently sensitive.

To distinguish between these possibilities, C57BL/6 spleen cells were sensitised *in vitro* to TNP-coupled syngeneic spleen cells¹². Table 2 shows that these spleen cells exerted high cell-mediated cytotoxicity on TNP-EL4 targets but no cytotoxicity on EL4 target cells. Various doses of cytotoxic effector cells (5×10^4 – 5×10^7) were injected intravenously into normal C57BL/6 mice, which were immediately challenged with 1% picryl chloride in olive oil on the ears. Table 2 shows that no contact sensitivity to picryl chloride was transferred by any dose of the cytotoxic spleen cells. It seems unlikely that this inability of the cytotoxic spleen cells to transfer contact sensitivity is caused by culturing these cells, because *in vitro* sensitised cytotoxic spleen cells transfer cell-mediated immunity to mice (ref. 15 and our unpublished results). Moreover, *in vivo* sensitised lymph node cells able to transfer contact sensitivity to TNP do not lose this ability after 5 d in culture (our unpublished results). This experiment (Table 2) therefore rules out the third possibility, since cells sufficiently active to be detected by the cytotoxicity assay did not transfer contact sensitivity even at very low doses. The second possibility also seems to be excluded because the population of cells cytotoxic to TNP-EL4 was nonetheless inactive in the contact sensitivity reaction. The first possibility is thus the most likely, implying that cells able to transfer contact sensitivity to TNP can be found in the absence of cells able to cause cytotoxicity to TNP-coupled target cells. Since both cytotoxicity to TNP-EL4 and contact sensitivity to hapten are functions of

T cells^{9–12}, they seem to be properties of two T-cell subpopulations.

Our results seem to conflict with experiments¹⁸ in which lymph node cells of CBA mice sensitised to either oxazolone or picryl chloride were able to lyse the allogeneic DBA/2 mastocytoma P815, provided phytohaemagglutinin was present¹⁸. This suggests that potentially cytotoxic cells are present in the lymph nodes of contact sensitised mice that are absent in normal mice; it does not necessarily mean, however, that the contact sensitivity cells themselves are cytotoxic, since the cytotoxicity could not be demonstrated to be target cell specific¹⁸. Arguing against the

Table 2 Inability of cytotoxic spleen cells to transfer contact sensitivity to TNP

Contact sensitivity		Increment in ear thickness at 24 h in 10^{-3} cm \pm s.e.	
Test animals			
Normal mice		3.6 \pm 0.4	
Mice sensitised on day -6		13.0 \pm 1.3	
Recipients of 5×10^7 non-immune spleen cells		4.8 \pm 1.5	
5×10^7 immune spleen cells		4.9 \pm 1.4	
5×10^6 non-immune spleen cells		3.8 \pm 1.1	
5×10^6 immune spleen cells		4.2 \pm 1.6	
5×10^5 non-immune spleen cells		3.9 \pm 1.7	
5×10^5 immune spleen cells		3.5 \pm 0.9	
5×10^4 non-immune spleen cells		5.0 \pm 2.4	
5×10^4 immune spleen cells		4.3 \pm 1.2	
Cytotoxicity		% Cytotoxicity \pm s.e.	
Source of cells	Target cells	4 h	8 h
C57 B16 spleen sensitised to TNP-C57 B16 spleen	EL4	0	0
C57 B16 spleen sensitised to TNP-C57 B16 spleen	TNP-EL4	16.4 \pm 1.4	48.1 \pm 3.7

C57BL/6 spleen cells (10^7 ml^{-1}) were sensitised *in vitro* to TNP-C57BL/6 spleen cells ($5 \times 10^5 \text{ ml}^{-1}$)¹². After 5 d cultures were collected and cytotoxic activity assayed on EL4 and TNP-EL4 target cells at an attacker to target cell ratio of 100:1. Spontaneous ^{51}Cr release was 2.9% h^{-1} for EL4 and 3.1% h^{-1} for TNP-EL4 targets. Spleen cells of cultures incubated with or without antigen were injected in various doses into groups of five normal recipients which were challenged with 1% picryl chloride. As controls, normal mice and mice presensitised once with picryl chloride on day -6 were included.

identity of contact sensitivity and cytotoxic cells is the finding that resensitisation of mice decreases the cytotoxic activity in the lymph nodes, while it increases their potential to transfer contact sensitivity (ref. 16 and our unpublished results).

It could be argued that the hypersensitivity cells are cytotoxic but do not lyse the TNP-EL4 target cell because they do not recognise the TNP group, but rather some larger moiety, including the determinant to which TNP is coupled. Evidence for this possibility has been presented with respect to the guinea pig^{17,18}. Recent experiments, however, have shown that cytotoxic mouse spleen cells, able to lyse the TNP-EL4, can recognise both the TNP group and TNP-modified self antigens¹¹⁻¹³ so that the failure of such cytotoxic cells to demonstrate contact sensitivity *in vivo* cannot be ascribed to inability to recognise the TNP group.

On the assumption that antigen recognition in the contact sensitivity reaction is similar to that in the cytotoxic reaction, our conclusion is that these reactions are performed by two distinct T-cell subpopulations.

Appearance of foetal antigens in somatic cells after interaction with heterologous sperm

GENETIC traits may be transferred to tissue cultured mammalian cells by interaction with viruses^{1,2}, nucleic acids^{3,4}, and cellular organelles such as metaphase chromosomes⁵⁻⁷, and by other cells⁸. Recent findings⁹ indicate that incubation of mouse spermatozoa with Chinese hamster bone marrow fibroblasts (CLM) results in uptake of sperm, morphological alterations, and, at a frequency of about 0.01%, subsequent mouse foetal antigen expression in the heterologous fibroblast progeny. To learn whether the efficiency of these processes can be enhanced, combinations of several species of sperm and target cells were studied in orienting experiments¹⁰.

The interaction of rat spermatozoa with Chinese hamster lung fibroblasts (DON) in tissue culture led to a higher yield of altered cells than was observed in the CLM-mouse sperm system. For collection of spermatozoa, the vasa deferentia were excised aseptically from adult Wistar strain rats, placed in Brackett's solution¹¹ plus 5% foetal bovine serum (FBS), and the living sperm were gently extruded into the medium without mincing the vas deferens. The sperm were separated from any remaining tissue clumps and washed by brief low speed centrifugation in this medium and adjusted to a concentration of 3×10^7 sperm

Fig. 1 Positive indirect immunofluorescence test for rat foetal antigens; ultraviolet light. *a*, Methanol-fixed DON Chinese hamster cells (from adult lung; American Type Culture Collection) 8 d after exposure to rat spermatozoa ($\times 248$). *b*, Methanol-fixed colony of DON cells 48 d after exposure to rat spermatozoa ($\times 157$). Cells were examined by the indirect immunofluorescence technique¹² by treating with Chinese hamster tissue-absorbed rabbit antiserum prepared against lyophilised skin-free trunk extracts of 17-21-d rat foetuses. After washing, the cultured cells were then stained with fluorescein-conjugated goat anti-rabbit IgG which had previously been absorbed with both Chinese hamster tissue extract and rat liver extract.

ml^{-1} . A suspension of 8×10^5 DON cells in 1.6 ml of Ham's F12 medium which contained 2% heat-inactivated FBS was mixed with 0.4 ml of the above sperm suspension. The ratio of sperm to cells was thus 15:1. After 2 h at 37 °C, 0.4 ml aliquots of the mixed cells were pipetted into 60-mm Petri dishes which contained microscope cover slips, and 4.6 ml of F12 medium plus 20% heat-inactivated FBS was added to each. Incubation was at 37 °C in a moist atmosphere of 5% CO_2 in air, and coverslips were withdrawn for examination after various times³. Control cultures of DON cells were incubated in parallel in the same final medium. Cell morphology was studied microscopically after fixation of monolayers with methanol and staining with Giemsa. By 48 h after admixture, about 50-55% of the DON cells seemed to have been penetrated by at least one spermatozoon. Colcemide-treated cultures were used to study metaphase chromosomes at various times after the first day of admixture.

Control DON cultures maximally showed a 3% incidence of binucleate cells and an occasional cell with three or four nuclei. In contrast, the fibroblasts in the mixed cultures showed a higher proportion of multinucleates beginning about 24 h after exposure to sperm, and at 96 h 14% were multinucleate. Although binucleation was the major morphological change in the 96-h mixed cultures, many of the

sperm-treated cells had four to six nuclei per cell. The proportion of cells in sperm-treated cultures with an approximately tetraploid number of chromosomes was also higher than in control populations. The modal chromosome number of the DON cells in control cultures was 22. Two days after exposure to rat sperm, 8% of the treated cells contained 40 or more chromosomes. Parallel control cultures at this stage had a 2% frequency of tetraploid cells and these possessed 44 chromosomes. The incidence of near tetraploids (cells with 40–50 chromosomes) 3 d after exposure to sperm had increased to 14%. Control values of tetraploid cells never exceeded 3% during the course of this study. Statistically, the increase over control values seen in rat sperm-treated cultures was highly significant, $P < 0.01$.

Progeny Chinese hamster cells at various times after interaction with spermatozoa were examined for the presence of rat antigen by the indirect immunofluorescence technique¹² using antiserum prepared in the rabbit against lyophilised preparations of saline extracts¹³ of days 17–21 Wistar rat foetal tissue, and staining with fluorescein-conjugated goat anti-rabbit IgG. The rabbit antiserum against rat foetal tissue extracts and the goat anti-rabbit IgG were absorbed with lyophilised extracts and whole tissue homogenates of adult Chinese hamster organs. The conjugated goat anti-rabbit IgG was further absorbed with lyophilised extracts of rat liver. At day 8, but not before that, approximately 0.5–1.0% of the cells examined in the ultraviolet showed positive cytoplasmic immunofluorescence (Fig. 1a). Of the positive cells, 18% had more than one nucleus, with binucleates predominating in this group; about 10% of the positive cells had a vacuolated cytoplasm. At days 14 and 36 after interaction with sperm, the proportion of progeny cells which exhibited positive cytoplasmic immunofluorescence increased to about 3% and 4% respectively. At day 39, cells were lightly seeded on coverslips to obtain individual colonies; after 9 d, all the cells in 1–2% of these colonies showed positive immunofluorescence (Fig. 1b).

Control DON cells and the washed rat spermatozoal preparations used were consistently negative with both immune and pre-immunisation rabbit serum; sperm-treated DON cells were negative throughout the 48-d period when tested with preimmune serum. Cultured Fisher rat embryo cells were positive with immune serum, but cultured adult Gunn rat liver cells¹⁴ and Morris hepatoma cells were negative. Rabbit antiserum against whole adult rat serum, after absorption with Chinese hamster tissue as above, gave positive immunofluorescence tests with the rat liver cells, but the tests were negative when applied to DON cells before and after mixture with rat sperm. Contaminating rat somatic cells in the sperm preparation would have been revealed in this test.

Experiments are under way to isolate and characterise the component(s) responsible for the immunofluorescence in individual positive clones, and to learn whether tumorigenicity can be demonstrated. In previous studies^{3,4}, synthesis of mouse antigens continued in CLM cells for at least a year of growth after interaction with mouse tumour cells or with DNA isolated from the latter; oncogenic potential was also acquired.

Although rigorous evidence that transcription and translation of rat sperm genetic material occurred in the DON population is not yet provided in these ongoing studies, it is unlikely that the results reported could have been due to rat somatic cells which had contaminated the sperm. Karyotype analyses never revealed the presence of rat chromosomes in hundreds of metaphase plates examined after coculture with the rat sperm. Immunofluorescence tests at times earlier than 8 d were consistently negative for rat foetal antigen. Furthermore, somatic cells of rat origin did not propagate when the sperm preparations themselves were subjected to the tissue culture conditions

used. We conclude that the intense cytoplasmic fluorescence observed after the interaction of rat sperm and DON cells was a result not of the presence of rat somatic cells or sperm proteinaceous material, but of the synthesis of rat foetal protein by the hamster cells.

The immunofluorescence data indicate that rat protein, most probably of foetal nature, persisted for at least 40–50 generations in Chinese hamster cells after mixture with rat sperm. Some proteins regarded as characteristic of the foetal stage of ontogeny are known to reappear in the adult just before the onset of and during malignant growth^{15,16}.

The data presented provide additional evidence that mammalian spermatozoa are capable of penetrating somatic cells *in vitro* and of affecting morphology and the normal process of mitosis. Independent confirmation of such penetration has appeared^{17,18}. The results in the present report suggest that sperm can act as vectors for the transfer and subsequent expression of genetic information in heterologous somatic cell systems. Whether the results are a consequence of a fertilisation-type reaction or are due to the presence of a recently discovered RNase-sensitive endogenous DNA-synthesising complex within sperm heads¹⁹, or to a still unknown mechanism is not yet clear. It is hoped that use of the sperm-somatic cell system will provide a further understanding of the significance of foetal proteins in oncogenesis^{20,21}.

We thank M. Steinglass for assistance, and Drs C. Tong and S. Witkin for discussions. This work was supported in part by a Public Health Service grant from the National Cancer Institute and a contract from the National Cancer Institute.

Sulphide-dependent anoxygenic photosynthesis in the cyanobacterium *Oscillatoria limnetica*

PROFOUND differences in structure and function separate the prokaryotic cyanobacteria (blue-green algae) from eukaryotic algae and plants, whereas oxygenic photosynthesis is considered to distinguish the cyanobacteria and eukaryotic plants from the

other phototrophic bacteria. The prevailing concepts on the cyanobacteria emphasise their prokaryotic nature and oxygenic photosynthesis. This combination of properties, among others, led to the suggestion that the cyanobacteria represent a group of possible progenitors of chloroplasts¹. While cyanobacteria typically exhibit oxygenic photosynthesis with two photosystems using electrons from water, it has been demonstrated that photosystem I of certain cyanobacteria can function *in vivo* independently in supporting virus production², heterocyst functions³ and even photoheterotrophic growth⁴. We have demonstrated anoxygenic photosynthesis in a cyanobacterium *Oscillatoria limnetica*, also capable of oxygenic photosynthesis,

Fig. 1 *a*, CO₂ photoassimilation by *Oscillatoria limnetica* in the presence of DCMU at different Na₂S concentrations and intensities of 704-nm wavelength light. Twice-washed, logarithmic phase cells were suspended in the growth medium (15 μg cell protein per ml) at various Na₂S concentrations with DCMU (5 μM) in 5-ml stoppered vials and preincubated for 2 h at 35 °C in light provided by a 60-W tungsten lamp (incident intensity of 2×10^4 erg cm⁻² s⁻¹). NaH¹⁴CO₃ was introduced to a final specific activity of 1.50 μCi μmol⁻¹, and the suspension incubated for 5 min under the actinic light provided by a Prado Universal-Leitz projector and filtered through a Corning HR 2-60 filter and then Schott Mainz sharp cutoff interference filter blocked to infinity peaking at 704 nm (11-nm half bandwidth). The incident intensity of the actinic light, varied by using a powerstat, was measured by a Yellow Springs Instrument Radiometer model 65. The cell suspension was filtered on glass filter paper (Whatman GF/C), washed with 40 ml 0.6 M trichloroacetic acid (4 °C), and cell radioactivity was counted by a gas-flow counter. Filters were washed with 5 ml of absolute ethanol to remove elemental sulphur, and protein was determined⁹. Various Na₂S concentrations in mM, were determined (methylene blue photometric method¹⁰) when the radioactivity was added. Concentrations (mM): ▽, 3.5; ×, 4.0; ◆, 2.8; ○, 2.0; △, 1.6; ▲, 5.9; □, 6.7; ■, 1.0; □, 8.5; ●, 0.0; ○, 9.5. *b*, Plot of photoassimilation rate (from *a*) at the saturation light intensity (1.0 μerg cm⁻² min⁻¹) as function of Na₂S concentration.

which was isolated from the anaerobic H₂S rich hypolimnion layer of the monomictic, hypersaline Solar Lake located on the desert margin of the Gulf of Elat, Israel⁵. During winter stratification, this layer is located below two plates of phototrophic sulphur bacteria (*Chromatium violescens* and *Prosthecochloris* sp.), and exhibits a dense cyanobacterial bloom with very high rates of primary production. We report here evidence for the photosystem I-driven CO₂ photoassimilation in *O. limnetica* with H₂S serving as sole electron donor through oxidation to elemental sulphur.

O. limnetica was grown in pure culture in a mineral medium prepared in Solar Lake water (96.7‰ chlorinity; 174.1‰ salinity), containing the major elements (g l⁻¹): KH₂PO₄, 0.33; NH₄Cl, 0.33; MgCl₂·6H₂O, 0.33; KCl, 0.33; NaHCO₃, 1.50; Na₂S·9H₂O, 0.075; vitamin B₁₂, 10⁻⁵; as well as SL 4 trace elements⁶; final pH was adjusted to 6.8 with HCl. Cultures were grown in completely filled glass-stoppered bottles, illuminated continuously by white fluorescent lamps (4,300 K, 20 W, incident light intensity 8×10^3 erg cm⁻² s⁻¹) at 35 °C.

The ability of the cyanobacterium to photoassimilate CO₂ in reactions driven by photosystem I alone and using Na₂S was demonstrated in the presence of DCMU under actinic light of 704-nm wavelength (Fig. 1*a*); no photoassimilation was observed in the absence of sulphide or light. Although the detailed mechanism of the sulphide oxidation is not known, the photosystem I-driven reaction and use of Na₂S are similar to that observed in many phototrophic sulphur bacteria. This photoassimilation is saturated by 704-nm wavelength light at an incident intensity of about 1.0 μerg cm⁻² min⁻¹. The plot of the photoassimilation rate at light saturation as a function of sulphide concentration shows an optimum around 3–4 mM Na₂S (Fig. 1*b*).

The fate of the sulphide, oxidised during the Na₂S-photosystem I-driven CO₂ photoassimilation in *O. limnetica* was determined from the distribution of the radioactive label in different sulphur fractions of the culture incubated with Na₂³⁵S in the presence of DCMU (Fig. 2). The decrease in ³⁵S²⁻ is accompanied by an almost equivalent increase in ³⁵S⁰. The small increase in ³⁵S₂O₃²⁻ and ³⁵SO₄²⁻ together are accounted for by chemical sulphide oxidation (as observed in the cell-free control). It seems that *O. limnetica* photo-oxidises S²⁻ quantitatively to S⁰. The rate of Na₂S oxidation in this experiment in the 10–25-h interval was 3.7 μmol Na₂S per mg protein per h; the rate of CO₂ uptake measured in identical conditions was 1.8 μmol CO₂ per mg protein per h. The stoichiometric relationship between CO₂ photoassimilation and H₂S oxidation derived, suggests the following equation:

Don't take a chance on labelled compounds

Don't take a chance on finding the right labelled compound. We make a range of over 1500; you can bet one of them's made for you.

You needn't take chances with purity, either. Our manufacturing, Quality and Stock Control remove the risk of disappointment.

For special products, our custom synthesis and labelling services make sure you get exactly the compound you need.

Don't gamble on delivery. We deliver to most parts of the world in a couple of days. We work through local distributors who

also act as our technical representatives.

Don't take risks with service.

Our technical staff are on call whenever you need help. They regularly visit most parts of the world, and you can rely on them for information and advice.

We publish general interest reviews and technical bulletins. All are free on request.

Finally, here's your chance to try us.

Write to us or 'phone. We'll send you our catalogue, the relevant literature and the name of your local agent.

make sure the label's ours

Rosetta Paperback Texts For Autumn 1975

Sensory Coding in the Mammalian Nervous System

George Somjen

This book is the most comprehensive review of research on the physiology of perception to date. Examining key investigations of the last 150 years, it focuses on the peripheral nervous system and the processing of information. Generous illustrations are provided.

386 pages

paperback: \$7.95

Fundamentals of Cybernetics

A. Ya. Lerner

This text is intended for those without a specialized knowledge of mathematics. Drawing from the works of Wiener, Shannon, Andronov, and Kolmogorov, the author traces the development of cybernetics. He presents the fundamental concepts of cybernetics such as movements, models, control, signals, and then progresses to their adaptation in behavioral and biological systems. Particular attention is given to the construction of artificial systems using game theory and communication theory.

294 pages

paperback: \$7.95

A Study of Brief Psychotherapy

D. H. Malan

Just how effective is short-term psychotherapy? Through a critical history of the development and practice of brief psychotherapy and a well-documented analysis of 19 case studies, the author carefully assesses the value of this therapeutic technique. Dr. Malan also develops dependable methods of evaluating the therapeutic results of brief psychotherapy. His psychodynamic method not only brings the precision of statistical analysis to an evaluation of clinical practices of the past, but also enables the practitioner to realize the conditions under which short-term psychotherapy will be most effective.

X-rays and Their Applications

J. G. Brown

This text provides a concise survey of the production, properties and applications of X-rays for technologists and students. It highlights • generation • measurement and detection • absorption and scattering • crystallography • diffraction • spectroscopy • refraction and reflection • health hazards • radiography. Accompanied by well-chosen examples and problems, it is one of the best and most complete guides in the field.

Fig. 2 Sulphide photo-oxidation by *Oscillatoria limnetica*. Cells, as described in Fig. 1, were suspended (25 µg cell protein per ml) in growth medium and flushed thoroughly with oxygen-free N₂. Cells were preincubated in the dark at 35 °C for 2 h, after which Na₂³⁵S was added anaerobically to a final specific activity of 0.1 µCi µmol⁻¹ and then incubated at 35 °C in continuous light provided by a 40-W tungsten lamp at a distance of 40 cm. Dark control and blank (without cyanobacteria) for chemical sulphide oxidation were run in parallel; in both cases sulphide oxidation did not exceed 12% throughout the experiment. Samples (5 ml) were filtered in a Swinnex filter holder through a 0.45-µm (average pore size) membrane filter directly into 2 ml of 0.11 M CdCl₂; filters were washed once with 10 ml of oxygen-free water, which was added to the filtrate (soluble S²⁻ fraction). The filter retaining both the particulate S⁰ and organic S fractions was homogenised in distilled water (5 ml) and transferred to a scintillation vial. These latter fractions were separated in another 5 ml sample of the experimental suspension. S⁰ and pigments were extracted by filtering the suspension and treating the glass filter with 5 ml of absolute ethanol, and were determined photometrically in the filtrate¹⁰. The filter retaining the organic S fraction was homogenised and transferred to a scintillation vial. The soluble S²⁻ fraction together with 0.1 nmol CdS carrier was transferred to an apparatus for anaerobic distillation¹¹. After flushing the apparatus with N₂, 10 ml of oxygen-free 6 N HCl was added. Sulphide was distilled into 10 ml of 0.1 M Zn acetate at room temperature with N₂ as carrier gas; 5 ml of the suspension of the ZnS produced was transferred to a scintillation vial for counting the ³⁵S²⁻ fraction. To precipitate sulphate, 5 ml of 2 M BaCl₂ was added to the undistilled remaining solution, diluted to 50 ml with water at room temperature. A 5-ml sample was transferred to a scintillation vial to determine both ³⁵SO₄²⁻ (as Ba³⁵SO₄) and dissolved ³⁵S₂O₃²⁻; the radioactivity in the remaining filtrate represented only the S₂O₃²⁻ fraction, although this was not demonstrated chemically. Insta-gel scintillation liquid (5 ml) was added to all the vials for counting in a Tri-carb scintillation counter. Radioactivity determinations of the various sulphur fractions are expressed as percentage of total sulphur at each sampling time. Experimental variation was no more than ±5%. ■, Blank H₂S; △, S⁰; ○, H₂S; ▲, S₂O₃²⁻; □, SO₄²⁻; ●, Organic S.

Elemental sulphur excreted from the cells was observed as typical refractile granules adhering to the cyanobacterial filaments (Fig. 3) or in the medium. The photosynthetic sulphur oxidation of Na₂S is similar in this respect to that of the Chlorobiaceae and some Chromatiaceae. In addition to the anoxygenic photosynthesis described here, this *O. limnetica* strain is capable of oxygenic photosynthesis and can readily shift to growth with either type of photosynthesis. The special physiological capacities of this strain represent an ecological advantage in an ecosystem such as the Solar Lake with an annual limnological cycle in which oxygenated conditions during holomixis alternate with high sulphide concentrations during stratification. *O. limnetica* is distributed throughout the lake at holomixis when the phototrophic bacteria disappear and thrives during stratification in the bottom layers, where the sulphide content is extremely high (40 mg H₂S per l) and prohibitive for the growth of the two other phototrophic bacteria.

The potency for using H₂ and other reducing compounds as electron donors for photoreduction of CO₂ has been demonstrated in special experimental conditions in certain oxygenic phototrophic organisms⁷, but growth was not supported. Attempts to grow other cyanobacteria in anaerobic conditions utilising H₂S as sole electron donor demonstrated that photosystem II is required⁸. *O. limnetica* represents the first case of an oxygenic phototroph that can grow anaerobically on H₂S. The significance in the evolution of oxygenic photosynthesis of a prokaryotic organism with both types of photosynthesis is highly suggestive. This strain also offers new possibilities for isolating photosystem II mutants.

We thank M. Avron of the Weizmann Institute for stimulating discussions and suggestions. A. Oren participated in the experimental work, M. Kessel provided the photographs and Binah Golek helped in the writing. This work was supported by a grant from the Deutsche Forschungsgemeinschaft.

Light inhibits the labelling of gangliosides in chicken retina

WE have reported that the labelling of brain gangliosides is more extensive in chickens given labelled glucosamine and subsequently exposed to light than in other chickens kept in the dark¹. The opposite result was obtained with rat brain². These effects parallel the influence of light on the general activity of the animals, and we could not decide whether the cause was a direct or indirect stimulus on the labelling process. Similar studies with the retina may help to solve this problem, for the retina is stimulated directly by light, and it is possible, by occluding one eye, to measure labelling in different conditions of illumination in one animal. We have now done such experiments and found that the labelling of retinal gangliosides varies in response to light: these changes are not attributable to systemic effects.

Labelling of retinal gangliosides in chickens maintained in the dark was greater than in those exposed to light (Table 1, experiments 1 and 2). Results were similar when one eye was occluded (experiment 4). In the latter case the difference was smaller and so the possibility remained that in experiments 1 and 2, a general effect was added to that of the incident light. But a substantial direct inhibition by light of retinal ganglioside labelling seems to be proved by our data.

Values for ganglioside labelling given in experiments 1 and 2 were normalised by the radioactivity of the acid-soluble fraction, but these ratios do not reveal the interesting fact that there was no difference between the acid-soluble fractions from the two groups of animals. The radioactivity of the acid-soluble fraction is shown in experiments 1a and 2a of Table 1. These results suggest that light did not affect the permeability to

labelled glucosamine or its derivatives, unless there was some effect in very limited areas of the retina.

The difference in the labelling of the sialyl moiety was at least partially responsible for the change in the gangliosides (Table 1, experiment 3). On the other hand, no individual ganglioside could be singled out as being specifically affected by light and this was investigated by chromatography. Chickens kept in the light or dark received, respectively, injections of ³H- or ¹⁴C-glucosamine or vice versa. Two hours later they were decapitated and the retinae pooled and minced. The gangliosides obtained from this pool were run on thin-layer chromatography and the ³H/¹⁴C ratio was determined every 0.5 cm of the chromatogram. In seven experiments we could not identify a zone with a ratio of labelling significantly different from the others.

There have been reports of the hyperpolarisation of the photoreceptor membranes in the vertebrate retina exposed to light, compared with that in the dark (for a review see ref. 3). It has been speculated that this hyperpolarisation interrupts the secretion of neurotransmitter from the synaptic endings⁴. For gangliosides, the precise step inhibited by light is unknown, but their participation in a presynaptic phenomenon is suggested by the high affinity of gangliosides for toxins of the presynaptic effect, such as tetanus and botulinum toxins^{5,6}.

In chickens another striking observation is that whereas exposure to light inhibited the labelling of gangliosides in the retina, it stimulated labelling in the telencephalon¹ the possibility that inhibitory events lead to decreased ganglioside labelling in the chicken retina exposed to light and that excitatory events lead to an overall increase in brain ganglioside labelling is worthy of investigation. The effect seen in the rat brain², which is opposite to that observed in chicken brain, requires explanation.

c.p.m. gangliosides per mg protein						
4	1	18	141 \pm 16	160 \pm 15	18.5 \pm 5	< 0.01

For experiments 1, 2 and 3, male Warren chickens were subjected, from hatching to the eighth day, to the conditions described previously¹, then maintained in the dark for 2 d and matched in pairs according to weight. After subcutaneous injections of 6-³H-glucosamine (specific activity 7.3 Ci mmol^{−1}; New England Nuclear, 0.7 μCi per g body weight), one animal of a pair remained in the dark while the other was exposed to 1,000 lx; chickens were decapitated 0.5 or 2 h later. For experiment 4, chickens were treated up to the tenth day as in the previous experiments; then they had one eye patched with black tape, injected with the radiochemical, exposed to light for 1 h and decapitated. Retinae were minced in water and gangliosides isolated by the trichloroacetic acid-phosphotungstic acid method⁷. For sialic acid determinations, gangliosides were hydrolysed in 0.1 N H₂SO₄ for 1 h at 80 °C and the hydrolysate was dialysed against water. Dialysed sialic acid was purified through Dowex I and determined by the thiobarbituric acid method⁸. Values given are means ± s.e.m.; the significance of the percentage differences was calculated by Student's *t* test for correlated data. Differences per cent are the means ± s.e.m. of individual differences for each matched pair. Values for retinae in light were considered 100%.

Influence of antidiuretic hormone on release of lysosomal hydrolase at mucosal surface of epithelial cells from urinary bladder

THE permeability change induced by antidiuretic hormone (ADH) in amphibian urinary bladder is limited to the apical membrane of epithelial cells rich in intracellular secretion granules¹. These granules, which may correspond to lysosomes², are observed to migrate to and fuse with the apical membrane of toad bladder epithelia treated with oxytocin or cyclic AMP³. We have extended these observations and found that ADH elicits a marked, time-dependent increment in the release of lysosomal hydrolases into the extracellular medium of epithelial cells isolated from amphibian bladder. This effect is abolished by specific antiserum to ADH and reduced by preincubation of cells with cortisol. Additional experiments with intact bladder verify that the hydrolases so released occur predominantly at the mucosal surface. Moreover, cortisol antagonises the enhancement of transepithelial water transport and membrane conductance attributable to ADH action.

Epithelial cells were isolated from the urinary bladders of *Rana catesbeiana* (Mogul-Ed Corp., Oshkosh, Wisconsin) by procedures described previously^{4,5}. These cells were maintained at 22 °C and suspended in Ringer solution constituted as follows: 104.5 mM NaCl, 2 mM KCl, 1 mM CaCl₂, 1 mM MgSO₄, and buffered at pH 7.4 with 2.125 mM Na₂HPO₄/0.375 mM NaH₂PO₄. Aliquots (2 ml; approximately 3 × 10⁶ cells) were incubated in the presence or absence of hormone for selected times in a Dubnoff shaking incubator. The epithelial cells were then sedimented by centrifugation at 400g for 5 min at +15 °C in a Sorvall RC2-B centrifuge. Sedimented cells were solubilised in 0.1 N NaOH:0.1% (v/v) Triton X-100 (Rohm and Haas) at 37 °C (24 h) and analysed for protein by the method of Lowry *et al.*⁶. The cell-free incubation medium was centrifuged further for 1 h at 105,000g in a Beckman-Spinco Model L preparative ultracentrifuge. Activities of representative lysosomal enzymes were determined on aliquots of the resultant particle-free supernatant fractions. Total enzyme activity per min in each experiment was then expressed relative to mg epithelial cell protein.

Cathepsin B1 (EC 3.4.22.1) activity was determined essentially

as described by Szego⁷. Fluorescence of the reaction product of cathepsin-mediated hydrolysis of the substrate, carbobenzyloxy-Ala-Arg-Arg-4-methoxy-β-naphthylamide (provided by Dr R. E. Smith), was measured at the emission peak of 410 nm on an Aminco-Bowman spectrophotofluorometer, using an activation beam of 292 nm; 4-methoxy-β-naphthylamine standards (provided by Dr Edward Smithwick, Jr) were analysed concomitantly. β-Glucuronidase (β-D-glucuronide glucuronohydrolase, EC 3.2.1.31) activity was determined at pH 4.5 by the method of Fishman⁷ as modified by Musa *et al.*⁸, using the substrate, phenolphthalein β-D-monoglucosiduronic acid (Sigma) at 37 °C. Acid phosphatase (orthophosphoric monoester phosphohydrolase, EC 3.1.3.2) activity was determined in the presence of 0.1 M sodium citrate buffer, pH 5.2, by the fluorometric method of Campbell and Moss⁹ as modified by Szego *et al.*¹⁰. Fluorescence of the product, α-naphthol, resulting from hydrolysis of the substrate, α-naphthylphosphate, was measured at the emission peak of 510 nm with an activation wavelength of 335 nm.

Epithelial cells in the several experiments were exposed to ADH (arginine vasopressin, Sigma), arginine vasopressin antiserum (provided by Drs A. A. Rosenbloom and D. A. Fisher), angiotensin II (Sigma), cortisol (free alcohol, Sharp and Dohme, West Point, Pennsylvania) or combinations of these agents. Cell viability in the presence and absence of these test reagents was evaluated by dye exclusion methods as described previously⁵. At least 95% of all cells used here excluded the dye, Trypan blue, at a final concentration of 0.05% in Ringer solution.

Determinations of activities of characteristic lysosomal enzymes released from epithelial cells incubated with and without ADH are presented in Table 1. Incubation in the presence of 1 mU ADH ml⁻¹ for 7.5 min resulted in statistically significant increases in the activities of acid phosphatase, β-glucuronidase and cathepsin B1, with mean increases of 66%, 24% and 167% over controls, respectively. Cells incubated with 1 mU ADH ml⁻¹ for 15 min responded in a similar manner. Acid phosphatase, β-glucuronidase and cathepsin activities rose by 37%, 15% and 133% over the values in controls. Although cells incubated with a higher concentration of hormone, 100 mU ADH ml⁻¹, for 15 min released a significantly greater activity of β-glucuronidase (*P* = 0.05), activities of the other lysosomal hydrolases did not vary significantly from those in the presence of 1 mU ADH ml⁻¹ (Table 1).

The effect of 1 mU ADH ml⁻¹ for 15 min in the presence of 50 p.p.m. antiserum specific for arginine vasopressin¹¹ was investigated. Control cells were incubated with antiserum alone. Activities of acid phosphatase and cathepsin in the incubation media of the hormone-treated groups were not significantly different from controls (Table 1). On the other hand, normal serum without hormone-specific antibody did not inhibit the

Activities of lysosomal enzymes are presented as mean ± s.e.m. with the number of determinations in parentheses. The significance of differences between hormone and control preparations was estimated by paired analysis with the Student's *t* test²⁴. In preliminary experiments, ADH was found to have no significant effect on enzyme activity *per se* in the assay conditions described in the text. In two additional experiments, 0.5 μg angiotensin II per ml, which is known to elicit a small hydro-osmotic effect in toad bladder²⁵, enhanced cathepsin activity to 110% of control cells incubated in the absence of the polypeptide for 15 min.

*Activity significantly different from control at *P* < 0.001.

†Activity significantly different from control at *P* < 0.01.

Table 2 Early mucosal release of cathepsin B1 elicited by serosal addition of ADH to intact bullfrog urinary bladder

Group	Incubation time (min)	Cathepsin B1 activity (nmol per min per mg dry weight)	
		Serosal side	Mucosal side
Control	7.5	0.03 ± 0.02 (8)	0.01 ± 0.00 (8)
ADH (100 mU ml ⁻¹)	7.5	0.03 ± 0.02 (8)	0.03 ± 0.00 (8)*
Control	15	0.03 ± 0.00 (7)	0.01 ± 0.00 (7)
ADH (100 mU ml ⁻¹)	15	0.03 ± 0.01 (7)	0.02 ± 0.00 (7)*

Intact bullfrog urinary bladders were incubated as sacs with Ringer solution in isosmotic conditions and otherwise as described before²⁶. The activity of cathepsin B1 was determined on aliquots of particle-free supernatant fractions collected from the mucosal and serosal media bathing the bladder sac. Total enzyme activity per min in each experiment was then expressed relative to mg dry weight of the bladder sac. All activities are presented as mean ± s.e.m. with the number of determinations in parentheses.

*Value significantly different from control at $P < 0.001$.

ADH effect (not shown). In the presence of ADH antiserum, therefore, the hormone does not induce increments of lysosomal enzyme activities in the extracellular medium.

The early influence of ADH on the differential release of cathepsin into the media bathing the serosal and mucosal sides of intact bullfrog urinary bladder is shown in Table 2. Incubation with 100 mU ADH per ml serosal solution for 7.5 min elicited a significant increment in cathepsin activity in the mucosal, but not in the serosal, medium. This result is consistent with the observations on isolated cells presented in Table 1 and further implies that the hormone-enhanced release of lysosomal hydrolases occurs predominantly at the apical surface of amphibian bladder.

In view of the known lysosome-stabilising action of cortisol¹², the effect of 100 mU ADH ml⁻¹ was tested for 7.5 min in isolated cells that had been preincubated with 3.3×10^{-6} M cortisol for 40 min. Cortisol alone had no significant effect on the extracellular activities of acid phosphatase (not shown; $n = 3$) and cathepsin (Table 3) as compared with paired controls incubated with the steroid vehicle, ethanol, at a final concentration of 0.1%. With addition of ADH following cortisol, activities of phosphatase and cathepsin, respectively, rose $19 \pm 10\%$ ($P > 0.20$, $n = 3$) and 67% over the values of controls exposed only to cortisol. These data reveal that membrane stabilisation by cortisol results in marked reduction of the effect of ADH on lysosomal enzyme release. Other experiments presented in Table 3 further indicate that cortisol acts to antagonise ADH-induced changes in the transport and electrical properties of bullfrog urinary bladder. Cortisol alone had no statistically significant influence on water permeability, short-circuit current or membrane conductance as compared with paired control hemi-bladders during a 40-min incubation period. The normal increment in water transport and membrane conductance in response to ADH¹³ was markedly reduced in bladders incubated with cortisol before exposure to ADH. The steroid, however, did not alter the effect of ADH on short-circuit current. These

data are consistent with previous reports which suggest that ADH has independent actions on sodium and non-electrolyte transport¹³.

Experiments in progress in our laboratory indicate that partially purified cathepsin B can elicit increments in lectin-mediated cellular agglutinability (for example, increase in membrane fluidity) at pH 7.4 (ref. 4). The action of ADH on non-electrolyte permeability in amphibian bladder is likewise considered to occur subsequent to the enhancement of membrane fluidity^{4,13,14}. The observed redistribution of membrane-associated particles on the apical surface of frog urinary bladder epithelium after oxytocin treatment is in accord with this hypothesis¹⁵. Since limited proteolysis at the membrane surface is known to alter cellular agglutinability^{16,17} and membrane fluidity¹⁸ in other cell types, the membrane action of the lysosomal protease, cathepsin B, should be investigated further.

The release of lysosomal enzymes into extracellular media or body fluids is thought to occur by a process of exocytosis following lysosomal membrane labilisation¹⁹. There is precedent for hormone-enhanced liberation of soluble proteins²⁰ and of lysosomal hydrolases^{10,21,22} into the particle-free medium of their specific target cell preparations. The potential physiological significance of these enzymes in hormone action has been reviewed^{2,4,23}. These data, taken in context with the present observations, suggest that ADH-enhanced mucosal release of membrane-bound hydrolases may contribute to the increments in membrane permeability and fluidity which characterise the hormone response at the apical membrane of epithelial cells rich in intracellular secretion granules.

Isolation of the two major epithelial cell populations from bullfrog bladder by centrifugation procedures and subsequent treatment of viable cells with ADH indicates that the hormone elicits lysosomal hydrolase release exclusively from "granular" cells and not from mitochondria-rich cells (Pietras, Naujokaitis and Szego, unpublished).

This study was aided by research grants from the US Public

Table 3 Counteractive influence of cortisol on transport and electrical properties of bullfrog urinary bladder and extracellular release of lysosomal hydrolase from isolated epithelial cells following addition of ADH

Group	Extracellular cathepsin B1 activity (nmol per min per mg protein)	Water permeability coefficient $\times 10^7$ (cm s ⁻¹)*	Membrane conductance $\times 10^4$ (mho cm ⁻²)	Short-circuit current (μ A cm ⁻²)
Control (0.1% ethanol)	0.03 ± 0.00 (3)	1100 ± 100 (4)	3.8 ± 0.2 (4)	31 ± 3 (4)
ADH (100 mU ml ⁻¹)	0.07 ± 0.00 (3)†	6400 ± 100 (4)†	4.6 ± 0.2 (4)†	48 ± 1 (4)†
Cortisol (3.3×10^{-6} M)	0.03 ± 0.00 (3)	950 ± 50 (4)	3.6 ± 0.3 (4)	30 ± 2 (4)
Cortisol and ADH	0.05 ± 0.01 (3)‡	3100 ± 300 (4)†	3.7 ± 0.2 (4)	47 ± 1 (4)†

Radioactive tracer and electrical techniques were used to study the transport of water and sodium, respectively, across bullfrog bladders mounted as flat sheets between two Lucite chambers as described previously^{13,14}. Transport and electrical measurements were made during the 60-min period following addition of ADH, cortisol or both hormones (cortisol being present for 40 min in mucosal and serosal media before serosal addition of ADH). Extracellular cathepsin B1 activity was determined as described in the text at 7.5 min following treatment of isolated epithelial cells with ADH, cortisol or both hormones. Ethanol, 0.1% final concentration, was present in all media.

*Values corrected as described before¹³ for the presence of unstirred layers (that is 160 μ m) in the bullfrog urinary bladder (R.J.P., unpublished).

Action of various antidepressant treatments reduces reactivity of noradrenergic cyclic AMP-generating system in limbic forebrain

STUDIES on the pharmacology of the noradrenergic cyclic AMP-generating system in slices from the limbic forebrain of the rat¹ and on adaptive properties of this system in conditions of persistent changes in the availability of noradrenaline (NA) have revealed that the system may serve as a model for the central NA receptor in this area, and that its sensitivity to NA increases or decreases when the availability of NA at the receptor site decreases or increases respectively^{2,3}. Thus, hypersensitivity of the system has been achieved by treatment with reserpine², a drug known to

precipitate occasionally severe depressive reactions in man⁴, and the syndrome of which, when elicited in animals, is widely used as a model for depression^{5–7}. Conversely, the monoamine oxidase (MAO) inhibitors, pargyline and nialamide, caused a marked reduction in the reactivity of the cyclic AMP-generating system to NA after chronic administration³. To determine whether or not antidepressant drugs which do not elevate the level of monoamines in brain share the effect of MAO inhibitors on the noradrenergic cyclic AMP-generating system, we studied the effect of the tricyclic antidepressants, desipramine and iprindole, on the reactivity of the system to NA. Desipramine blocks the uptake of NA through the neuronal membrane^{8,9} whereas iprindole neither blocks the neuronal uptake of NA nor alters its metabolism or turnover^{10,11}, but is nevertheless a potent antidepressant^{12–14}. In addition, we have tested the effect of electroconvulsive treatment (ECT), as it is generally accepted to be one of the most effective treatments for severe depression¹⁵.

Male Sprague-Dawley rats (initial weight 180–220 g), housed four or five to a cage and kept in standard laboratory conditions (12-h light-dark cycle; food and water *ad libitum*) were used. The rats receiving antidepressant drugs were injected intraperitoneally with 10 mg kg⁻¹ d⁻¹ of desipramine or iprindole hydrochlorides for 4–8 weeks. Control rats received a corresponding volume of saline. Reserpine (Serpasil, CIBA-Geigy) was administered for 4 d at a dose of 2.5 mg kg⁻¹ d⁻¹. ECT was given by passing a current (100 mA; 300 ms) through ear clip electrodes. Controls had the electrodes attached, but no current was passed. Normal animals received ECT daily for 8 d, and the reserpine-treated animals received it for 4 d, approximately 2 h before each injection of reserpine.

The rats were decapitated at specified intervals after the last treatment, their limbic forebrain area (containing olfactory tubercles, septal and accumbens nuclei; anterior parts of the hippocampus and of the amygdaloid nuclei) was dissected as described previously², divided along the midline, chopped into blocks of approximately 0.5 mm³ and incubated at 37 °C following slightly modified² procedures of Kakiuchi and Rall¹⁶ and Palmer *et al.*¹⁷. After a 30-min preincubation period and change of the incubation medium (NaCl 118 mM; KCl 5 mM; CaCl₂ 2.5 mM; KH₂PO₄ 2 mM; MgSO₄ 2 mM; NaHCO₃ 24 mM; EDTA-Na 0.02 mM; glucose 10 mM; O₂-CO₂ 95:5; pH 7.4), the slices were incubated for an additional 14 min. At this time, slices from one half of the forebrain were exposed to a specified concentration of NA, whereas those from the corresponding

*Time after last injection of drug, ECT or handling.

†Difference of levels of cyclic AMP between preparation exposed to NA and non-exposed preparation from corresponding half of the limbic forebrain. Numbers in parentheses denote number of pairs. Basal levels of cyclic AMP were not changed by the antidepressants or ECT (17.8 ± 2.6 pmol per mg protein in saline-treated and 35.1 ± 1.4 pmol per mg protein in handled group).

‡P < 0.05.

§P < 0.01.

¶P < 0.001 (difference between control and experimental; drug and/or ECT group).

||Not significantly different from control (handled group), but different (P < 0.05) from handled, reserpine-treated group.

half served for the determination of the basal level of cyclic AMP. The reaction was terminated 10 min later by homogenisation of the tissue slices in 3.5 ml 0.3 N HClO₄; a 0.5-ml aliquot of the homogenate was used for the determination of the protein concentration by the method of Lowry¹⁸. Cyclic AMP was isolated by ion-exchange chromatography and assayed by the method of Gilman¹⁹. All values were corrected for recoveries and cyclic AMP was expressed in pmol per mg protein. Student's two-tailed *t* test was used for the statistical evaluation of the data.

The effect of chronic treatment with tricyclic antidepressants and of ECT is shown in Table 1. Prolonged treatment with antidepressant drugs reduced the responses of the cyclic AMP-generating system by approximately 70%. A much shorter treatment with ECT reduced the response by 30% in rats killed 18 h after the last shock, and, interestingly, by 50% in rats killed a day later. Reserpine treatment (2.5 mg kg⁻¹ daily for 4 d) enhanced the response to NA by approximately 50%, confirming earlier results². Concomitant ECT practically abolished the increased cyclic AMP response to NA (Table 1). The response to NA has not been significantly changed in preparations from rats receiving tricyclic antidepressants for a period of 2 weeks or less. Our results complement data obtained with MAO inhibitors, which depressed the cyclic AMP response to NA by 50–60% after prolonged but not short term treatment³ and reveal a common mode of action at post-synaptic noradrenergic receptor sites for antidepressants regardless of their action at presynaptic sites, and for ECT. The decreased reactivity to NA after ECT may provide the biochemical basis for the antagonism by ECT of stimulant effects induced by combined treatment with desipramine and Ro4-1284 (ref. 20) or amphetamine²¹, and for the potentiation by ECT of the reserpine syndrome and α -methyltyrosine-induced catalepsy²¹.

Our data emphasise the dissociation of acute biochemical effects of antidepressant drugs from their therapeutic action, which occurs only after chronic treatment for weeks. The demonstrated decrease in noradrenergic receptor function as a consequence of various antidepressant treatments—pharmacotherapy and ECT—should focus future neurochemical research on the elucidation of molecular mechanisms of altered aminergic receptor function and provide a new theoretical framework for studies on both pathogenesis and therapy of affective disorders.

We thank USV Pharmaceutical Corporation and Wyeth Laboratories for desipramine and iprindole, respectively. Our studies were supported by the US Public Health Service.

Tubulin in postsynaptic junctional lattice

TUBULIN, the primary protein of microtubules^{1,2}, has been identified as a major soluble protein in isolated synaptosomes^{3,4}. Indirect evidence for the presence of tubulin in the synaptosomal plasma membranes themselves has been accumulating for some time. Colchicine-binding activity, used as an assay for the presence of tubulin^{1,2}, has been found in synaptosomal plasma membranes^{5–7}. These membranes, prepared by several different techniques, all show a prominent protein band of apparent molecular weight 52,000–53,000 when solubilised and electrophoresed in sodium dodecyl sulphate–polyacrylamide gel systems^{8–12}; such gel techniques applied to well characterised microtubule preparations yield molecular weights for tubulin which have been reported to range from 52,000 to 56,000 (refs 1 and 2), the precise value depending on the particular

Fig. 1 Densitometer scans of the proteins of synaptosomal plasma membranes (a) and isolated postsynaptic junctional lattices (b), stained with Coomassie brilliant blue after electrophoresis in 7.5% polyacrylamide gels with a continuous buffer system of 0.1% (w/v) sodium dodecyl sulphate, 0.1 M Tris-HCl, pH 7.4. The sample buffer contained dodecyl sulphate–protein 2:1 (w:w) and 0.2% 2-mercaptoethanol in 5mM Tris-HCl, pH 7.4. Triangles indicate the tops of the gels, and the arrows indicate the bands with an apparent molecular weight of 50,300.

Fig. 2 Tracings of autoradiographs of the tryptic maps obtained from proteins labelled with ^{125}I after electrophoresis in sodium dodecylsulphate-polyacrylamide gels¹⁸. Crossed circles mark the origins, solid circles the peptides common to all three maps and open circles the remainder. The starting proteins were: *a*, the 50,300-dalton protein from synaptosomal plasma membranes; *b*, the 50,300-dalton protein from isolated postsynaptic junctional lattices; *c*, electrophoretically pure tubulin.

electrophoretic system used. Sequential solubilisation of synaptosomal plasma membranes with Triton X-1000 and N-lauroyl sarcosinate yields isolated postsynaptic densities¹³ whose major protein has a molecular weight of 53,000 (ref. 14), and similarly digestion of the synaptosomal lipid unit membrane by sodium deoxycholate results in isolated postsynaptic junctional lattices¹⁵ with a major protein of approximate molecular weight 53,000 (ref. 12). We report here the identification of tubulin in the postsynaptic junctional lattices of rat forebrain both by two-dimensional electrophoresis of ^{125}I -labelled tryptic peptides and by electron microscope immunohistochemistry.

Synaptosomal plasma membranes were prepared from rat forebrain by the method of Jones and Matus¹⁶, with the slight modifications that all sucrose solutions and the lysis buffer contained 50 μM calcium chloride and the sucrose solutions were also buffered with 5 mM HEPES, pH 7.4. Postsynaptic junctional lattices were isolated by incubating the membranes at a final protein concentration of 1.7 mg ml⁻¹ in 10% (w/v) sodium deoxycholate, 1 mM phenylmethylsulfonylfluoride, and 50 μM calcium chloride for 2 h at 37 °C, followed by dilution with a two-thirds volume of distilled, deionised water and pelleting at 100,000g for 1 h at 4 °C (see ref. 12). Of the membrane protein, 98% is solubilised by this procedure. Figure 1 shows densitometer scans of the proteins of the starting synaptosomal plasma membranes and the isolated postsynaptic lattices, stained with Coomassie brilliant blue after electrophoresis in sodium dodecyl sulphate-polyacrylamide gels. The band in each gel indicated by the arrow has an apparent molecular weight of 50,300 and comigrates with added rat brain tubulin prepared by the repeated polymerisation method of Shelanski *et al.*¹⁷. These bands were excised from the gels, particular care being taken to omit the shoulder (molecular weight 54,300) on the membrane

peak. The tubulin band from a similar gel of electrophoretically pure tubulin, itself prepared by elution from polyacrylamide gels of once repolymerised tubulin, was also excised. The proteins from these slices were eluted, concentrated, iodinated by a chloramine T reaction, performic acid oxidised and then digested with trypsin and the resultant peptides purified, using the methods of Bray and Brownlee¹⁸. Samples of these peptides were electrophoresed at 3,000 V in 2 dimensions on Whatman 3 MM paper, first for 75 min in pH 6.5 buffer (10% pyridine, 0.3% acetic acid) and then for 75 min in pH 2.1 buffer (8% acetic acid, 2% formic acid). The electrophoretograms were exposed to X-ray film for 42–168 h. Figure 2 shows the autoradiographic maps of the tyrosine-containing tryptic peptides of the 50,300-dalton protein from synaptosomal plasma membranes, the 50,300-dalton protein from postsynaptic junctional lattices, and tubulin. The number of spots in the tubulin map (20) agrees well with the expected number of tubulin tyrosine peptides (18–19) (ref. 19) and the number of iodinated peptides previously reported (18–20) (ref. 18). The three tryptic fingerprints are almost identical, and thus the three proteins from which they were derived are strikingly homologous.

Approximately 300 μg of tubulin which had been excised from polyacrylamide gels of once-repolymerised rat brain tubules, eluted, and concentrated, was intramuscularly injected into a rabbit in 50% Freund's complete adjuvant and comparable booster shots administered at 10-d intervals. This technique has been used to produce monospecific antibodies to actin²⁰ and myosin²¹. Figure 3 is an electron micrograph immunohistochemically illustrating the cellular localisation of the rat brain tubulin antigen in rat cerebral cortex²². The peroxidase reaction product is clearly visible on dendritic microtubules and is also present at the postsynaptic lattice of the visible axodendritic synaptic junction. In all the material we have examined, incubation of brain tissue with anti-tubulin serum in the immunoperoxidase procedure produced staining only in association with microtubules and the postsynaptic junctional lattices²³.

We have thus established that the major postsynaptic

Fig. 3 Electron micrograph of a rat cerebral cortex slice which was incubated with rabbit anti-tubulin serum, washed with phosphate buffered saline (PBS), incubated with peroxidase-labelled sheep anti-rabbit gamma globulin serum, washed again with phosphate-buffered saline, and the immunohistochemical staining developed by 30 min exposure to a solution of 5 mg 3,3'-diaminobenzidine in 10 ml of PBS, pH 7.2, to which had been added 10 μl of hydrogen peroxide.

junctional lattice protein and tubulin share a common antigen and are so closely similar in primary structure that their tryptic digests are virtually identical. These results confirm the earlier tentative identification of tubulin as the major component of the postsynaptic density, where it probably has an important structural role in providing a matrix for more specialised proteins of functional importance in synaptic transmission^{12,14}. Some form of functional role for the tubulin itself cannot, however, be discounted at present. It has been proposed that "linkage elements" associated with the cell membrane and pharmacologically similar to tubulin are involved in the selective cellular control of particular membrane components²⁴. Although such elements may be present throughout the synaptosomal plasma membrane, more of these "tubulin-like" molecules would be expected in specialised areas, especially ordered arrays such as are present at the synaptic junction¹⁵. The observed distribution of tubulin in the synaptosomal plasma membrane and postsynaptic junctional lattice precisely matches the hypothesis that tubulin functions as a membrane-associated molecular linkage element.

Post-transcription control of isocitrate lyase induction in the eukaryotic alga *Chlorella fusca*

WE have shown previously¹ that poly(A)-containing RNA can be isolated from the green alga *Chlorella fusca* 8p (ref. 2) and that this RNA has messenger-like properties, as it is polydisperse and stimulates polypeptide synthesis *in vitro* in a wheat embryo system. We show here that the *Chlorella* protein isocitrate lyase has been identified as a product of *in vitro* translation of poly(A)-containing RNA, so confirming messenger function in this fraction. We have used the *in vitro* translation system as a means of assaying for the presence of isocitrate lyase message sequences in poly(A)-containing RNA isolated from *Chlorella* cultured under different conditions, and we report here that slow-growing non-induced cells may contain high levels of mRNA for this enzyme although the enzyme is not synthesised.

Isocitrate lyase is an adaptive enzyme^{3,4}, and its synthesis

Fig. 1 SDS gel electrophoresis of immunoprecipitated protein produced by *in vitro* protein synthesis, in a wheat embryo system. Total *Chlorella* RNA was separated on a cellulose column into an unadsorbed fraction and an adsorbed fraction (described fully in ref. 1). The adsorbed fraction was poly(A)-containing RNA of which 46 µg were added to one cell-free protein synthesis assay (○). The unadsorbed fraction from the column was mostly rRNA of which 50 µg were added to a second cell-free protein synthesis assay (△). A control assay where no RNA was added was also performed (●). *Chlorella* RNA was isolated as described previously¹, from a culture containing 2.5×10^7 cells ml⁻¹ which had been incubated in the dark with 0.1% sodium acetate for 90 min (acetate-adapting *Chlorella*). The cell-free protein synthesis mixtures were prepared by the method of Roberts and Paterson¹⁰ as described previously¹, but scaled up to a total volume of 400 µl, and were incubated at 30 °C for 2 h. The radioactive amino acid included was ³⁵S-methionine (10 µCi, 200 Ci mmol⁻¹). After incubation all assays were treated as follows: 5 µg ovalbumin and 50 µl anti-ovalbumin serum were added and precipitates formed after 2 h at room temperature were removed by centrifugation (preprecipitation, see text). Supernatants were mixed with carrier antigen (5 µl pure isocitrate lyase, 0.75 mg ml⁻¹) and 25 µl of specific anti-isocitrate lyase serum. After 16 h at 4 °C the immune precipitate was recovered by centrifugation, washed three times with 1 ml of 5 mM Tris-acetate, pH 7.5, dissociated with 20 µl of 0.2 M NaOH for 15 min at room temperature and neutralised by addition of 20 µl of 0.2 M HCl and 60 µl of 8 M urea. The resulting mixtures were made 1% in sodium dodecyl sulphate (SDS) and 0.01 M in 2-mercaptoethanol and incubated at 100 °C for 2 min before electrophoresis in 7.5% polyacrylamide gels¹¹. After electrophoresis the gels were sliced into 1-mm segments and the radioactivity in each slice was determined as previously described¹. Br, Bromophenol blue marker. The upper part of the figure shows absorbance at 650 nm of two gels run under identical conditions and loaded with pure isocitrate lyase (ICL) or insulin (Ins), cytochrome c (Cyto c), myoglobin (Myo) and bovine plasma albumin (BPA). Both gels were stained with Coomassie brilliant blue.

is induced in *Chlorella* when acetate is added to darkened cultures. There is temporal restriction of isocitrate lyase synthesis in synchronous *Chlorella* cells³ and its synthesis is prevented when photosynthesis is possible⁶ or when glucose is present in the medium^{3,4}, indicating a catabolite repression control mechanism in addition to the inducing effect of acetate. When fully induced, isocitrate lyase is an unusually abundant enzyme constituting 7% of total soluble protein⁷. This suggested that isocitrate lyase mRNA might be a relatively abundant RNA species.

Preliminary experiments showed that rabbit antiserum which was raised against isocitrate lyase purified to homogeneity⁸, precipitated less than 0.05% of the radioactivity in an extract from an autotrophic *Chlorella* culture grown in the presence of ³⁵S-sulphate⁹, when the antiserum was added in the presence of sufficient unlabelled pure isocitrate lyase to enable immune precipitation. When unlabelled pure isocitrate lyase was added to wheat embryo cell-free protein synthesis assays and precipitated with specific antiserum, the immune precipitate was contaminated with proteins resulting from nonspecific adsorptions. In the experiment described under Fig. 1 this nonspecific effect was reduced by a preprecipitation step, where products of cell-free protein synthesis assays were mixed with ovalbumin which was precipitated with a specific anti-ovalbumin serum.

Figure 1 shows the results of electrophoretic analysis of the proteins precipitated from cell-free protein synthesis assays by anti-isocitrate lyase serum. The addition to the cell-free system of poly(A)-containing RNA isolated from *Chlorella* cultures in the process of isocitrate lyase synthesis, resulted in synthesis of a protein *in vitro*, which was absent from assays which had received either no added RNA, or *Chlorella* rRNA. The peak of radioactive protein had the same electrophoretic mobility as pure isocitrate lyase, which is also shown in Fig. 1. Isocitrate lyase is a tetrameric protein and under the conditions used to dissolve the immune precipitate, it was completely dissociated into subunits of molecular weight ~ 47,000.

To minimise the problem of nonspecific adsorption of proteins to the antibody, the anti-isocitrate lyase serum was immobilised by cyanogen bromide linkage to Sepharose beads (anti-ICL-Sepharose). When pure isocitrate lyase was adsorbed by a column of anti-ICL-Sepharose, only a small proportion of the enzyme was displaced by 0.01 M NaOH whereas the remainder was displaced quantitatively with 0.1 M NaOH (Fig. 2). Figure 2 also shows the elution of radioactive protein from an anti-ICL-Sepharose column which had been loaded with the products of a cell-free protein synthesis assay, primed with poly(A)-containing RNA isolated from *Chlorella* in the process of isocitrate lyase synthesis. Gel electrophoresis of protein eluted by 0.1 M NaOH is shown in Fig. 3, where it can be seen that a profile of peaks closely resembling those obtained with pure isocitrate lyase was obtained. Preparation of samples for electrophoresis as performed in this experiment did not completely dissociate isocitrate lyase and a distribution of monomers and multimers was obtained. It is evident that protein adsorbed to the anti-ICL-Sepharose column and

Fig. 2 Elution of products of *in vitro* protein synthesis from a column of anti-isocitrate lyase serum covalently linked to sepharose (anti-ICL-Sepharose). The data are for products of *in vitro* translation of poly(A)-containing RNA from acetate-adapting *Chlorella*, in a 200 μ l cell-free mixture incubated at 30 °C for 3.5 h, but otherwise as described under Fig. 1, (●). Pure isocitrate lyase was also adsorbed to a column and eluted (○). To prepare anti-ICL-Sepharose, 2 ml of anti-isocitrate lyase serum (15 mg ml⁻¹ protein) were linked to 1 g of cyanogen bromide-activated Sepharose 4B following the manufacturer's instructions (Pharmacia). Anti-ICL-Sepharose, suspended in 0.5 M NaCl, 0.005 M sodium phosphate, pH 7.0 was packed in 1-ml columns and washed with 5 ml of 0.005 M sodium phosphate, pH 7.0 (phosphate buffer) before use. Products of cell-free protein synthesis assays or pure isocitrate lyase (40 μ g) were applied to the column and allowed to adsorb for 1 h at room temperature, before washing through with 20 ml of phosphate buffer (buffer wash). Elution with 2 ml of 0.01 M NaOH was followed by a further 20 ml of phosphate buffer (0.01 M NaOH eluate). Lastly 2 ml of 0.1 M NaOH were applied and this also was followed with 20 ml of phosphate buffer (0.1 M NaOH eluate). Hot trichloroacetic acid-insoluble radioactivity in each fraction was counted as previously described¹. Elution of pure isocitrate lyase was followed by measurement of absorbance at 280 nm.

which was only displaced by the higher NaOH concentration with largely isocitrate lyase. This, in turn, demonstrated the presence of message sequences for isocitrate lyase in poly(A)-containing RNA from *Chlorella*.

In the conditions of batch culture which we used⁸, autotrophic *Chlorella* cultures grew exponentially until cell number density reached about 10⁷ cells ml⁻¹, then growth rate declined as they became more and more light limited, finally ceasing at a density of about 5 × 10⁷ cells ml⁻¹. At no stage of growth does isocitrate lyase synthesis occur

Table 1 Fractionation of *in vitro* translation products of *Chlorella* poly(A)-containing RNA on anti-ICL-Sepharose columns

Source of poly(A)-containing RNA	Buffer wash	Hot TCA-insoluble radioactivity (c.p.m.)		% of total c.p.m. in 0.1 M NaOH fraction
		0.01 M NaOH eluate	0.1 M NaOH eluate	
(1) Acetate-adapting cells	103,600	25,000	13,500	9.4
(2) Control (minus RNA)	50,000	530	1,900	3.6
Exponential autotrophic cells	50,900	5,400	1,600	3.0
Light-limited autotrophic cells	44,100	2,800	5,800	12.3

Data assembled from Fig. 2 (1) and Fig. 4 (2). Pooled fractions were sampled and hot trichloroacetic acid-insoluble radioactivity measured. For (1) cell-free translation mixtures were incubated for 3.5 h at 30 °C. For (2) cell-free translation mixtures were incubated for 2 h at 30 °C.

Fig. 3 SDS disc gel electrophoresis of *in vitro* translation products eluted with 0.1 M NaOH from anti-ICL-Sepharose columns (see Fig. 2). *In vitro* translation of poly(A)-containing RNA from acetate-adapting *Chlorella* is described in Fig. 1 and fractionation of the translation products on anti-ICL-Sepharose is shown in Fig. 2. Protein in the 0.1 M NaOH eluate was subjected to electrophoresis (○). Products of a control *in vitro* translation assay (minus RNA) were also fractionated (Fig. 4) and protein in the 0.1 M NaOH eluate subjected to electrophoresis (●). Both samples were prepared for electrophoresis as follows: pooled column fractions were made 5% in trichloroacetic acid; precipitated protein was recovered by centrifugation, washed twice with 5 ml of ethanol, resuspended in gel buffer¹² containing 1% SDS and 0.01 M 2-mercaptoethanol and heated to 100 °C for 2 min. Electrophoresis was carried out in 15% SDS gels¹² after which they were cut into 1-mm slices which were incubated overnight at 37 °C in a toluene-based scintillation mixture including 5% Protosol (New England Nuclear) and counted for radioactivity. The upper part of the figure shows absorbance at 650 nm of a gel which had been run with 20 µg of pure isocitrate lyase and stained with Coomassie brilliant blue.

unless acetate is the sole available carbon and energy source.

Poly(A)-containing RNA was isolated both from exponentially growing autotrophic cultures and from light-limited cultures. Analysis of products of *in vitro* protein synthesis directed by these RNA samples, using anti-ICL-Sepharose columns, is shown in Fig. 4. When poly(A)-containing RNA from exponentially growing cells was tested, the amount of radioactive protein in the 0.1 M NaOH eluate from the column was the same as the control, in which the cell-free protein synthesis assay was performed without added RNA (see also Table 1). In contrast, addition to the cell-free system of poly(A)-containing RNA isolated from light-limited autotrophic cells resulted in isocitrate lyase synthesis as demonstrated by the larger amount of

radioactive protein in the 0.1 M NaOH eluate (Fig. 4 and Table 1). In a separate experiment (results not shown) this protein was found to have the same electrophoretic mobility as pure isocitrate lyase (analogous to Fig. 3).

The absence of detectable isocitrate lyase mRNA in exponentially-growing, photosynthesising cells and its presence in cells adaptively synthesising isocitrate lyase, provides evidence for the operation of a transcriptional control, but it is also firmly demonstrated that a post-transcriptional control can operate, since messenger accumulates without being translated, as low light limits the growth rate.

When *Chlorella* cells use acetate as their sole carbon source, the activity of the glyoxylate cycle is necessary for the synthesis of intermediary metabolites which are normally more readily produced by photosynthesis or the metabolism of glucose¹³. The synthesis of isocitrate lyase correlates with the detection of glyoxylate cycle activity in this strain of *Chlorella*³ and the present study demonstrates that the adaptive synthesis of the enzyme in rapidly growing cells follows the accumulation of mRNA from previously undetectable levels. This evidence provides further support for the conclusion that synthesis of the enzyme in rapidly growing cells is initiated by transcription, which was previously drawn tentatively from the effect of inhibiting functional RNA synthesis⁴. There is therefore a parallel with the control of gene expression in prokaryotic cells¹⁴⁻¹⁶.

Fig. 4 Elution from anti-ICL-Sepharose of *in vitro* translation products of poly(A)-containing RNA extracted from autotrophically grown *Chlorella*. Poly(A)-containing RNA was isolated¹ from an autotrophic *Chlorella* culture collected during exponential growth (cell number density, 6.5×10^6 cells ml⁻¹), (○) and from a culture which had become light-limited (cell number density, 1.44×10^7 cells ml⁻¹) (●). These poly(A)-containing RNA samples were translated in the wheat embryo cell-free system in a final volume of 200 µl, but otherwise as described in Fig. 1. Translation products were fractionated on anti-ICL-Sepharose columns as described in Fig. 2. Products of a control cell-free assay to which *Chlorella* RNA had not been added, were also fractionated (▲). Hot trichloroacetic acid-insoluble radioactivity was measured.

The direct estimation of isocitrate lyase mRNA, however, provides evidence for at least one additional control point acting at the post-transcriptional level, which is more specific in its requirements for release of enzyme synthesis. In light-limited cells the supply of intermediary metabolites is sub-optimal and the accumulation of isocitrate lyase mRNA is initiated, but this is not sufficient to cause synthesis of the enzyme. Therefore the restriction of isocitrate lyase synthesis to conditions when acetate is present to act as substrate for the glyoxylate cycle and with no alternative carbon source available, is achieved by the operation of post-transcriptional control. This control may be lacking in the thermophilic strain of *Chlorella*, in which darkening without addition of acetate is sufficient to promote maximum synthesis of isocitrate lyase¹⁷.

It is possible that the mRNA which is accumulated, but not translated, in light-limited cells is held at a stage requiring further processing, such as specific cleavage from a large nuclear precursor (HnRNA), or export from the nucleus. This interpretation supposes that the wheat embryo *in vitro* protein-synthesising system can translate unprocessed messenger, as can *Xenopus* oocytes¹⁸. There is evidence, however, that post-transcriptional control is exerted when mRNA is fully processed and is already supporting isocitrate lyase synthesis. Glucose, which makes the glyoxylate cycle redundant, causes an immediate cessation of enzyme synthesis^{4,6}, in contrast to the gradual cessation of synthesis which follows the use of an inhibitor to prevent further transcription⁴. Many metabolite levels in *Chlorella* are altered by changes in carbon source^{19,20} and these metabolites could operate post-transcriptional control by modifying the binding of a regulator protein to mRNA^{21,22}, or by modifying the nascent protein to produce either abortive folding²³ or enhanced sensitivity to protease attack²⁴.

Whatever the precise mechanism of post-transcriptional control for isocitrate lyase synthesis, the existence of this control in eukaryotic algae, taken together with evidence for the operation of similar mechanisms in mammalian cells²⁵, suggests that post-transcriptional controls may be common in eukaryotes.

Is Fanconi's anaemia defective in a process essential to the repair of DNA cross links?

FANCONI'S anaemia (FA) is a rare autosomal recessive disease of man, characterised by a progressive hypoplastic pancytopenia associated with diverse congenital anomalies^{1,2}, spontaneous chromosome breakage³ and predisposition to leukaemia and other cancers^{4,5}. Lymphocytes from FA patients were found to be excessively susceptible to chromosome breakage by di- or polyfunctional alkylating agents^{6,7}, and this was interpreted as a possible indication of defective DNA repair of the FA cells⁷. Seeking evidence for this, I have tested lymphocytes from FA patients for their chromosome response to mono- and difunctional mitomycins in relation to the cell cycle phase at the time of treatment, and have found that FA cells have a specific defect in the repair of pre-aberration lesions induced by difunctional mitomycin; the lesions are possibly DNA cross links of the interstrand type. The rationale of this experiment was the knowledge that if damage to DNA is left unrepaired it can be linked causally to the formation of chromosome aberrations by a process that resides in semiconservative DNA replication⁸⁻¹². Since the repair of DNA damage is a rate-limiting process, the treatment of repair-proficient cells in early G₁ would leave more time for repair before the damage is fixed into chromosome aberrations during the S phase, and consequently would result in fewer chromosome aberrations than treatment during the transition from G₁ to S. In the repair-deficient cells, however, DNA damage induced by treatment in any position of G₁ would be linked maximally to the formation of chromosome aberrations.

Heparinised venous blood was obtained from two male patients with FA aged 6 and 7 yr (identified as FA7 and FA9) and a normal healthy person as a control. The procedure has been described before¹⁰. Briefly, a series of whole-blood microcultures was set up using basal medium NCTC-109 supplemented with 20% foetal calf serum and 3% phytohaemagglutinin, and fixed for chromosome preparation after 70-74 h of incubation. At various times before fixation, cells were treated for 30 min with difunctionally reacting mitomycin C (MMC) or its monofunctional derivative, decarbamoyl mitomycin C (DCMMC, a gift from Dr K. Nakano, Kyowa Hakko Kogyo Co.) in conjunction with ³H-thymidine, and incubation was continued for a corresponding recovery time in culture medium free of test compounds. The preparations were processed for autoradiography and analysed for their metaphase labelling pattern and the presence of chromosome aberrations in labelled and unlabelled mitoses.

The changes in metaphase labelling index are shown in Fig. 1. Even in the absence of mitomycins, FA cells passed more slowly than normal through S and G₂. Moreover, in contrast to normal cells, most FA cells collected at 70-74 h were still in their first mitosis, as indicated by a comparatively small amount of the second maximum metaphase labelling index. Treatment with mitomycins reduced the rate of progression through the cell cycle, and the effect was more marked when the FA cells were treated with MMC. Figure 2 shows that ³H-thymidine alone had little effect on chromosomes of normal or FA cells. Although DCMMC was less efficient than MMC, both induced significant chromosome aberrations of the chromatid type. The

Fig. 1 Changes in the proportion of labelled mitoses as a function of time from treatment. At various times before fixation, cells were treated for 30 min at 37 °C with DCMMC or MMC which was made up in medium TC-199 containing ^3H -thymidine ($1 \mu\text{Ci ml}^{-1}$) or with ^3H -thymidine alone, washed and re-incubated for the indicated recovery time in the medium NCTC-109 supplemented with 20% foetal calf serum and $5 \times 10^{-5} \text{ M}$ cold thymidine. All cultures were fixed at any time between 70 and 74 h of total incubation time with a 2-h prefixation treatment with colchicine. Chromosome preparations were made according to the standard air-drying technique using hypotonic treatment in

0.9% sodium citrate before fixation in methanol-acetic acid (3:1). Preparations were processed for autoradiography using Kodak NTB3 emulsion. Metaphase labelling index was determined on 250-400 mitoses. +, Normal cells treated with ^3H -thymidine alone; \times , FA9 cells treated with ^3H -thymidine alone; \square , normal cells treated with DCMMC ($20 \mu\text{g ml}^{-1}$); \blacksquare , FA7 cells treated with DCMMC ($50 \mu\text{g ml}^{-1}$); \circ , normal cells treated with MMC ($0.5 \mu\text{g ml}^{-1}$); \triangle , normal cells treated with MMC ($1.5 \mu\text{g ml}^{-1}$); \bullet , FA7 cells treated with MMC ($0.1 \mu\text{g ml}^{-1}$); \blacktriangle , FA9 cells treated with MMC ($0.1 \mu\text{g ml}^{-1}$).

Fig. 2 Changes in the frequency of chromatid aberrations in labelled (solid lines) and unlabelled (dashed lines) mitoses as a function of time after treatment. After recording of the labelling-pattern and location of mitoses, the silver grains were removed and chromatid aberrations were scored in the preselected mitoses (100 for each point). Chromatid aberrations scored are gaps, breaks and exchanges occurring at the chromatid level. The scoring does not include the cells in S phase at the time of

treatment and recovered at their second mitosis. The frequencies of induced aberrations are expressed as the net amount of induced aberrations, that is, observed frequencies minus spontaneous levels, which were 0.07, 2.00 and 2.14 per normal, FA7 and FA9 cell, respectively, as determined in their 72-h cultures, which were kept untreated during incubation. The symbols used are the same as in Fig. 1

patterns of the chromosome response of normal cells to DCMC and MMC and that of FA cells to DCMC were as predicted for repair-proficient cells. With respect to formation of chromosome aberrations, the S phase, more particularly its very beginning, was the most sensitive stage. The chromosome aberrations were less frequent in unlabelled mitoses that were in the pre-DNA-synthesis stage at the time of treatment, and their frequencies varied with the recovery time, being maximum in late G₁, decreasing with increasing recovery time. When tested with MMC, however, FA cells were most sensitive at G₁ and, moreover, yielded a constant rate of aberrations when treated in various parts of G₁, and a decreasing yield as the S phase progressed. This pattern of chromosome response to MMC is comparable with that of xeroderma pigmentosum cells to 4-nitroquinoline-1-oxide¹⁰. These cells have an impaired capacity to repair DNA alterations induced by ultraviolet light and some chemicals, including 4-nitroquinoline-1-oxide^{13,14}. These results indicate that in the FA cells pre-aberration lesions induced by DCMC can be repaired, but those induced by MMC at any time before DNA synthesis are not repaired and link maximally to the chromosome aberrations formed during the subsequent S phase. Since the FA cells are also abnormally susceptible to chromosome breakage by the psoralen-plus-light reaction⁷, which is highly specific to native DNA and induced interstrand cross links¹⁵, it is probable that the MMC-induced lesions that are irreparable in the FA cells are DNA cross links of the interstrand type.

In bacteria, repair of cross links is controlled by *uvr* and *recA* genes, and it has been suggested to be mediated by a sequential process involving excision of one cross linked arm and a subsequent recombination of homologous duplexes^{16,17}. When the excision repair capacity of FA lymphocytes was tested, their level of DCMC- and MMC-stimulated unscheduled DNA synthesis was comparable with that of normal cells. Thus if a repair mechanism like that proposed for cross links in bacteria can apply to human cells, the FA cells could be defective in the later step of the sequential repair process. A simple application of this repair process, especially an excision step by endonucleolytic incision cannot, however, easily explain the repair of cross links in mammalian cells.

With respect to differing sensitivity of cell stage to chromosome breakage, xeroderma pigmentosum cells respond to MMC as the repair-proficient cells while they are deficient in unscheduled DNA synthesis induced by MMC (my unpublished data). Similarly, rat kangaroo cells show a chromosome response of the repair-proficient type to sulphur mustard¹² in spite of their unresponsiveness, in terms of unscheduled DNA synthesis, to ultraviolet light¹⁸. Furthermore, cross links induced by sulphur mustard can be repaired in mouse L cells¹⁹ which have very little ability to excise ultraviolet damage²⁰. These observations suggest that, unlike bacteria in which sensitivity to MMC, sulphur mustard and ultraviolet light is commonly associated with the *uvr* gene^{21,22}, mammalian cells can repair cross links by a process independent of the excision ability responsible for the repair of damage induced by ultraviolet light. The identification of the site of the primary defect in FA cells awaits elucidation of such a repair process. My results, however, strongly suggest that FA cells are defective in a biological system which constitutes an essential step in the repair of DNA interstrand cross links.

I thank Dr A. Ozawa for his cooperation. This work was supported by grants from the Ministry of Education and the Ministry of Health and Welfare of Japan.

Organisation and evolution of *Drosophila virilis* heterochromatin

CENTRIC heterochromatin in *Drosophila* metaphase chromosomes is organised into large blocks which show various degrees of condensation in prometaphase¹ and various degrees of decondensation when living cells are Hoechst treated². By sequential staining with the fluorescent dyes Hoechst and quinacrine, three different types of blocks are distinguishable in *D. virilis*. Each block seems to contain only one DNA satellite and similar staining blocks, along with their respective satellite, appear or disappear as units during speciation; this was first suggested from a study of *D. hydei* sibling species¹ and here confirmed for the *D. virilis* group.

The *virilis* group species in Fig. 1 are phenotypically almost indistinguishable and interspecific crosses, excepting with *D. ezoana*, produce fertile offspring³. Maps of their polytenised euchromatin are identical except for inversions and translocations^{3,4}. Heterochromatin differs drastically within the group as evidenced by acrocentric fusions, heterochromatin elimination and the presence or absence of various satellite DNAs in centromeric heterochromatin (Fig. 1).

Sequential staining of *D. virilis* metaphase chromosomes with Hoechst, quinacrine and Giemsa reveals three different types of heterochromatin blocks enabling one to identify each chromosome by the blocks it possesses (Fig. 1). The remaining species lack H⁺ or Q⁺ blocks so their chromosome arms, being of similar size, cannot usually be identified. In interspecific hybrids, however, such as the *D. virilis* × *D. texana* hybrid of Fig. 2, the euchromatic arms of *D. texana* chromosomes are often somatically paired with homologous and identifiable arms of *D. virilis* chromosomes. Here, by comparing the fluorochromatically differentiated heterochromatin of homologous arm pairs from different species, one sees that *D. texana* has 65% less heterochromatin than *D. virilis* and lacks block α₁. The *virilis* group's heterochromatin is thus organised into distinct blocks and similar blocks are lost or gained during speciation (Fig. 1).

In *D. virilis*, there seems to be a 1:1 relationship between the three different fluorochromatic blocks and the three different DNA satellites which is based on indirect evidence from various sources. *D. melanogaster* shows five satellites which are located in centric heterochromatin⁵⁻⁷. Some of these satellites, as localised by *in situ* hybridisation, are confined to only one or a few chromosomes⁷. Four satellites are homogeneous non-interspersed tandem repeats of a small oligonucleotide; the repeats are at least 600 kilobases (kb) long⁷. *D. virilis* satellites present a similar story. ³H-RNA complementary to satellite I hybridised *in situ* to heterochromatin of all chromosomes⁸; however, since heterologous satellite hybrids have melting points close to the *in situ* annealing conditions used⁹ and autoradiographic resolution is limiting, the exact location of satellite I was not determined. Sarcosyl lysates of *D. virilis* cells, having

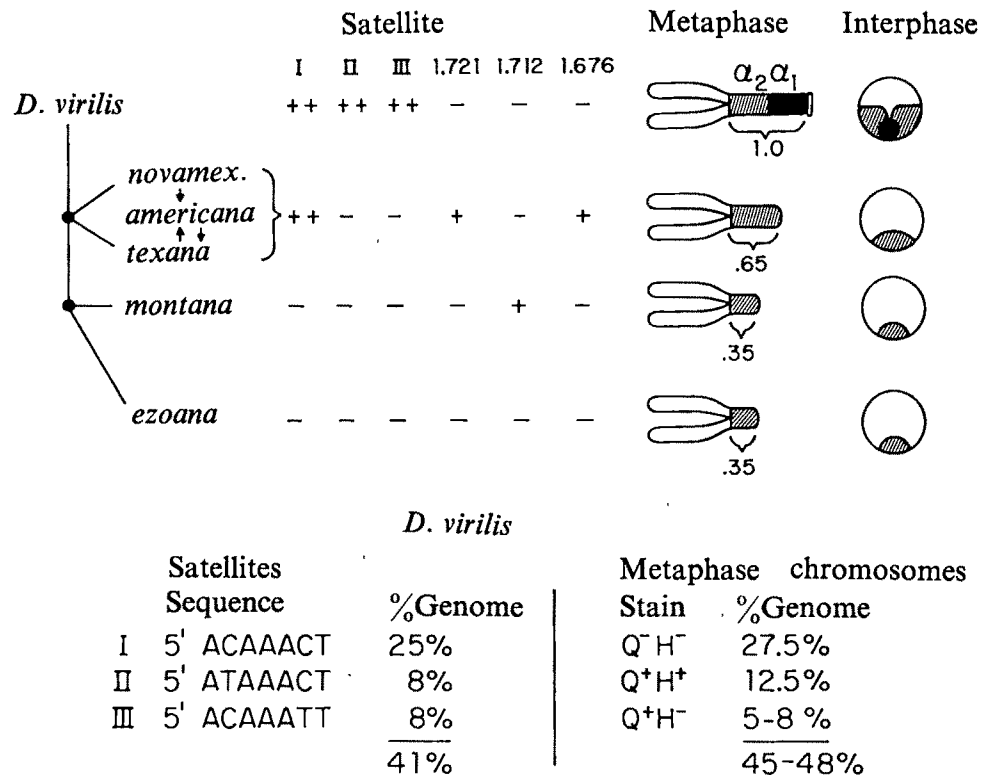

Fig. 1 Phylogenetic relations of the *D. virilis* group^{3,4} are presented as family tree. Species which evolved from *D. montana* and *D. ezoana* are not included. Satellites common to each species^{10,11} are indicated. Minor satellites, which comprise less than 5% of the genome, are designated by their buoyant density in neutral CsCl. One stylised chromosome arm and an interphase nucleus from female larval neuroblasts of each species are presented. Alpha heterochromatin of each *D. virilis* chromosome is composed of two fluorochromatic blocks. The distal α_2 block is Q⁻H⁻ while the proximal α_1 block is Q⁺H⁺ for chromosomes X, 2 and 4, Q⁺H⁻ for chromosome 3, and Q⁻H⁻ for chromosome 5 (ref. 1). Chromosomes from the remaining five species show less heterochromatin and no Q⁺ or H⁺ blocks of heterochromatin. All six species have the same amount of euchromatin²; the amount of heterochromatin is expressed as prometaphase chromosome length of heterochromatin/length euchromatin where the amount of euchromatin is normalised to 1.0. For example, *D. americana* and *D. texana* each have an average of 0.65 units of heterochromatin associated with each euchromatic chromosome arm. *D. novamexicana* has approximately the same amount of heterochromatin as these two previous species even though most of it is associated with one chromosome pair. Centric heterochromatin aggregates into a chromocentre in diploid (right hand column) and polytene interphase nuclei. *D. virilis* interphase nuclei are particularly interesting because the heterochromatic chromocentre is divided into three regions possibly representing the three different satellites²⁴. The central region is H⁺ and partially separates the two Hoechst-dull regions. The other *virilis* group species lack H⁺ or Q⁺ material in their chromosomes and interphase nuclei. The size of their interphase chromocentres parallels their content of metaphase heterochromatin. The table shows the three heptanucleotide sequences which, when tandemly repeated, constitute the three *D. virilis* satellites^{10,11}. The percentage of the diploid genome each satellite comprises is shown next to its base sequence. The percentage prometaphase chromosome length devoted to each permutation of Hoechst-quinacrine brightness is from previous data¹ and is arranged to correspond to the satellite data. Estimates of percentage genome devoted to a particular 'type' of chromatin are rather inexact because of differential chromatin condensation during various stages of mitosis.

DNA molecules averaging at least 90 kb in length, show excellent satellite separation after analytical buoyant density ultracentrifugation^{8,10,11}. Thus, similar to the findings with *D. melanogaster* satellites, one heptanucleotide is repeated many times without interdigitation and forms almost pure repeating heptanucleotide tracts at least 90–180 kb long. By extending these molecular weight findings a little, one can imagine a pure repeating heptanucleotide tract 15,000 kb long. This is just enough DNA to fill one fluorochromatic block (one-quarter of a chromosome) (Fig. 3). Each block, being homogeneous in its DNA, would show a homogeneous fluorescence after quinacrine or Hoechst staining and this is indeed seen¹. There are three satellites in heterochromatin and three differently staining blocks of heterochromatin. The amount of each satellite and amount of heterochromatin showing a particular quinacrine-Hoechst permutation can be arranged to correspond quite well (Fig. 1). This correspondence ascribes satellite I to the Q⁻H⁻ blocks. Satellite I, having the highest GC content of the three satellites, would be predicted to correspond to the most weakly fluorescing blocks¹²⁻¹⁴ as it does. Satellites II and III are absent from *D. americana*, *D. texana* and *D. novamexicana*^{10,11} as are their ascribed Q⁺H⁺ and Q⁺H⁻ blocks (Figs 1 and 2). In hybrid cells containing somatically paired chromosomes, this loss seems to be a simple excision of the Q⁺H⁺ or/and Q⁺H⁻ block (Fig. 2). When comparing the sibling species *D. hydei*, *D. neohydei* and *D. eohydei*, the same relationships hold^{11,16}. Here

the presence of fluorochrome bright and dull blocks parallel the presence of AT-rich and GC-rich satellites, respectively. Here again the polytene banding patterns are almost identical, only the non-polytenised centric heterochromatin is different between species. The lack of Q⁺ or H⁺ material in *D. americana*, *D. texana* and *D. novamexicana* cannot be due to lack of a specific protein which confers fluorochrome-bright properties to heterochromatin because the staining properties of each chromosome in *virilis* × sibling species hybrids remains unchanged. Finally, the absence of satellite I in *D. ezoana* and *D. montana* is paralleled by an extreme loss of Q⁻H⁻ heterochromatin. The simplest model of chromosome organisation in accord with all existing data is that each fluorescent block of centric heterochromatin in *D. virilis* contains one continuous repeating DNA molecule consisting of a single heptanucleotide repeated about two million times which, when coated with protein, condensed and packaged, forms a homogeneous appearing block of centric heterochromatin with fluorescent properties determined by the heptamere it contains (Fig. 3).

In chromosomes of the *virilis* group, certain alterations of heterochromatin occurred, were selected for and subsequently fixed during evolution. Knowing these alterations, we can now make some statements concerning the organisation and evolution of heterochromatin in *Drosophila*.

(1) Heterochromatin is more taxonomically divergent than external morphological characteristics^{1,15}; one can more easily

identify the fly by looking at its metaphase chromosomes than by looking at the fly itself. Speciation has proceeded with the loss or gain of large heterochromatin blocks (Fig. 1) although the euchromatic arms have remained relatively unchanged^{3,4}.

(2) The 2-3 metacentric in *D. texana* (Fig. 2) and a similar X-4 metacentric in *D. americana* were thought to represent simple Robertsonian fusions of two *D. virilis* acrocentrics^{10,11} but this is obviously not true (Fig. 2). If these metacentrics actually evolved from the present *D. virilis* chromosomes, then fusion was preceded by, or concomitant with, loss of α_1 blocks, loss of the short Q^+H^- right arms and relocation of the *virilis* centromeres into Q^-H^- heterochromatin. Although the exact process of chromosome fusion that actually took place remains unknown, it was irreversible and more complex than the simple, reversible Robertsonian fusions which occur between telocentric chromosomes during speciation in mice.

(3) Satellite DNA cannot account for all the heterochromatin in any of the *virilis* group species (Fig. 1). This is most evident in *D. ezoana* which lacks satellite but, like all *virilis* group species, has some heterochromatin in each chromosome. The complete absence of satellite DNA in many of these species^{10,11}, even in alkaline CsCl gradients, argues against the presence of a cryptic satellite. Thus, each Q^-H^- block in *D. virilis*, *americana*, *texana* and *novamexicana* must be composed of two DNAs, satellite I and non-satellite, and two different Q^-H^- blocks which cannot be distinguished by fluorometric means. The non-

satellite block would correspond to the heterochromatin remaining *D. ezoana* and *D. montana*. Being ubiquitous within the group, this block must contain the heterochromatic genes and about the euchromatin-heterochromatin junction (Fig. 3). The heterochromatin of the *D. melanogaster* X is similarly Q^-H^- (ref. 1), lacks satellite DNA⁷ and contains the sex-linked heterochromatic genes¹⁶.

Fig. 3 The single DNA molecule, which runs the length of the chromosome²⁰, shows three successive levels of DNA organisation in *D. virilis* heterochromatin. The basic level is a tandemly repeated heptanucleotide (—)^{10,11}. The second level, a 2-30+ repeating unit, was detected in *D. melanogaster*^{17,18} as equally spaced restriction endonuclease sensitive sites (*, ○) similar to bovine satellite I DNA¹⁹. Lastly, the 2-30-kb repeats are packaged into large fluorochromatic blocks which contain about 17,000 kb = one-quarter of a chromosome. The α_1 block and the short arm opposite the centromere (C) are fluorochrome bright and contains satellites II or III. The dull α_2 block contains satellite I in its proximal region and non-satellite DNA in its distal region. Although Peacock *et al.*⁵ reported satellite DNA in euchromatic polytene bands 21CD of *D. melanogaster*, I find this hybrid to have a 15 °C lower melting point than centromeric hybrids. Thus, 21CD DNA differs from centromeric satellite⁸ and euchromatic regions may indeed be free of true centromeric satellite DNA.

(4) Similar blocks of heterochromatin and similar satellites appear or disappear during speciation even though these similar blocks or satellites are usually on many different chromosomes. This may imply selection for interchromosomal interaction of like blocks of heterochromatin. In interphase nuclei, the heterochromatin aggregates into a chromocentre wherein similar blocks of heterochromatin aggregate on to themselves to the exclusion of others (Fig. 1). This aggregation also seems to direct somatic non-disjunction in colcemid-anaphase nuclei of *D. virilis*¹. There are three types of chromosome-chromosome pairing in *Drosophila* somatic nuclei: somatic pairing of identical euchromatin, centric aggregation of identical or similar centric heterochromatin and ectopic pairing of polytene bands which are often morphologically¹⁷ or chemically^{18,19} similar. All three pairings involve two chromosome segments which contain identical or suspiciously similar DNA. Selection for interchromosomal pairing of heterochromatin would explain the simultaneous appearance or disappearance of quasi-dispersed satellites during speciation.

I thank Dr David E. Comings for support and review, and Drs B. J. Conner and T. A. Okada for review.

Fig. 2 Neuroblast prometaphase chromosomes from hybrid *D. virilis* × *D. texana* third instar larvae sequentially stained with Hoechst, quinacrine and Giemsa to distinguish each chromosome. Neuroblast metaphase preparations were stained with Hoechst¹, destained (three overnight rinses in pyridine), stained with quinacrine and finally stained in Giemsa. The pyridine removal method enables one to initially scan a Hoechst-stained slide when chromosomes are brightest and subsequently stain with the dimmer (quinacrine) fluorochrome. *a*, *c* and *d*, Hoechst stained; *b*, Giemsa stained from *a*. *D. virilis* chromosomes are indicated by number. Somatic pairing of homologous euchromatic arms allows one to unambiguously identify each *D. texana* arm because the homologous *D. virilis* arm is identifiable. For example, in (*a*), the upper arm of the 2-3 metacentric of *D. texana* pairs with the Q^+H^- *D. virilis* chromosome 3. The lower arm pairs with the Q^+H^+ *D. virilis* chromosome 2. Even though it is difficult to distinguish between the two Q^+H^+ chromosomes 2 and 4 in *D. virilis*, one can easily do this in such hybrids where *D. virilis* 2 must pair with one arm of the *D. texana* 2-3 metacentric. This sibling species-somatic pairing method should be quite useful for chromosome identification in many other dipteran groups. Alpha heterochromatin condenses earlier than euchromatin^{1,8} and is most apparent in Giemsa stained preparations of very early prometaphase (*b*). The Q^+H^+ blocks of α_1 heterochromatin condense even earlier than α_2 heterochromatin¹ so the H^+ blocks in early prometaphase (*a*) appear relatively smaller than the H^+ blocks in late prometaphase (*c* and *d*). *D. texana* chromosomes look like *D. virilis* chromosomes which have lost the α_1 block of heterochromatin.

Segregation of RD-114 and FeLV-related sequences in crosses between domestic cat and leopard cat

TYPE C viruses of the RD-114 (ref. 1) group have been isolated, either spontaneously or after chemical induction, from cell cultures of the domestic cat (*Felis catus*)^{2–4}. Nucleic acid sequences related to the RD-114 genome are in the DNA of all domestic cats^{5–8}. Thus these viral genomes are transmitted vertically from parent to offspring as integral components of cat cellular DNA. Although the family Felidae consists of closely related animals, only four *Felis* species have been found to contain RD-114-related sequences. These include the domestic cat, the European wildcat (*F. sylvestris*), the sand cat (*F. margarita*), and the jungle cat (*F. chaus*); other members of the Felidae lack nucleic acid sequences related to RD-114 (ref. 9). The observation that RD-114 is partially related to the endogenous baboon type C viruses^{10–12} and that sequences related to RD-114 are found in the cellular DNA of all Old World monkeys led to the postulate that this group of viruses originated from an endogenous primate type C virus¹³ transmitted horizontally to the germ line of ancestors of certain *Felis* species during the Pliocene or early Pleistocene somewhere in the region of the Mediterranean basin⁹.

A second distinct group of type C viruses, the feline leukaemia viruses (FeLV), also has been isolated from domestic cats¹⁴. Although FeLVs are horizontally transmitted among domestic cats, genes partially related to the RNA genome of FeLV are found in *F. catus* DNA¹⁵ and in the DNA of the other species of Felidae which contain RD-114 related nucleic acid sequences¹⁶. Viruses of the FeLV group are also postulated to have been transmitted to an ancestor of these *Felis* species, but to have originated from a rodent rather than a primate source¹⁶.

The leopard cat (*F. bengalensis*) is a spotted wildcat found throughout South-east Asia which lacks RD-114 and FeLV-related DNA sequences (RD[–], FL[–])⁹. Since leopard cats produce viable offspring when bred with domestic cats (RD⁺, FL⁺), we studied the segregation of both sets of virogenes in F₁ hybrids and in the progeny of a backcross to the RD[–], FL[–] parent. The cellular DNA of the F₁ hybrids contains half the number of copies of each set of sequences. The RD and FL virogenes segregate together in the backcrossed animals in a manner consistent with their localisation at a single chromosomal site.

The reassociation kinetics obtained by hybridising ³H-DNA transcripts of viral RNA to cellular DNA can be used to estimate relative gene frequencies by determination of half *C*₀*t* values (the midpoint of the renaturation curve)¹⁷. The number of gene copies can also be estimated by plotting reassociation kinetics as the reciprocal of the fraction of unhybridised ³H-DNA against *C*₀*t* (Wetmur–Davidson plot)¹⁸. In such plots, the slope is proportional to the number of copies of those sequences measured. Using RD-114 ³H-DNA probes,

multiple copies of virus-related sequences can be detected in the cellular DNA of stray domestic cats, domestic cats reared in a germ-free environment (Merck, Sharp and Dohme, West Point, Pennsylvania) and in European wildcats (*F. sylvestris*) (Fig. 1a and Table 1). The *C*₀*t*_{1/2} values ranged from 120 to 170. In contrast, the cellular DNA of the leopard cat completely lacks RD-114 related sequences. The *C*₀*t*_{1/2} values for the self-annealing of non-repetitive domestic cat cellular DNA, and for the hybridisation of the ³H-DNA RD-114 probe to the DNA of a canine thymus cell line infected with RD-114, ranged from 1,800 to 2,000 (Fig. 1, Table 1). Given that *C*₀*t*_{1/2} values of 1,800–2,000 are obtained with genes present in a single copy per haploid genome, domestic cat and European wildcat cellular DNAs contain 10–13 copies of RD-114-related sequences per haploid genome. Since these copies represent a family of diverging gene sequences only partially related to one another¹⁹, the calculated number of copies may be an underestimate^{20,21}.

Leopard cat males were mated to domestic cat females and the F₁ hybrids studied. These DNAs contain a complete complement of sequences related to the RD-114 probe, but only half the number of copies present in the domestic cat parent (Fig. 1a). The *C*₀*t*_{1/2} values (275–350) represent, as a minimum estimate, five to seven virogenic copies per haploid genome. Two kittens obtained from an F₁ hybrid female backcrossed to the leopard cat (Fig. 2) were also studied. Figure 1a shows that kitten No. 1 contains all the RD-114-related information, but only half the number of copies (*C*₀*t*_{1/2} 280), like the F₁ parent, whereas kitten No. 2 (from the same litter) lacks RD-114-related DNA sequences like its leopard cat parent. These results suggest that the multiple copies of RD-114 re-

* Cellular DNA was extracted from various organs (spleen, liver, kidney, lung) and hybridised to RD-114 and FeLV ³H-DNA as described in Fig. 1. Domestic cats Nos 2 and 3 were from the germ-free colony of cats at Merck, Sharp and Dohme; animals from this colony have never been found to be positive for infectious feline leukaemia virus. F₁ hybrid cats Nos 1, 2 and 3 and 4 belong to three separate litters.

† *C*₀*t*_{1/2} values represent the midpoint of the reannealing curves¹⁷.

‡ The approximate number of copies per haploid genome of sequences related to either RD-114 or FeLV were estimated from reciprocal plots (Fig. 1). The number of copies is determined by the ratio of the slope of each line to the slope of the line described by the reassociation of non-repetitive domestic cat cellular DNA (*C*₀*t*_{1/2} = 1,800–2,000; see also ref. 19). In the case of RD-114, where two sets of viral sequences can be detected in cellular DNA, the number of copies listed is the average of the two populations.

§ CCC clone 6 is from a continuous line of domestic cat kidney fibroblasts and is not releasing type C virus^{2,3}, and RD-114/FCf2Th and FeLV/FCf2Th are a dog thymus cell line infected, respectively, with RD-114 (ref. 1) or with the helper virus from the Gardner–Arnststein²³ strain of feline sarcoma virus.

Fig. 1 Analysis of reassociation kinetics by the method of Wetmur and Davidson¹⁸ of RD-114 and FeLV ³H-DNA probes to cat cellular DNAs, and of domestic cat unique sequence cell DNA self-association. The ³H-thymidine-labelled DNA probes were synthesised from detergent-disrupted type C virus in the presence of actinomycin D as described²⁷. The specific activity of the ³H-DNA was 1.7×10^7 c.p.m. μg^{-1} . The ³H-DNA probes contained 60–66% of their respective 70S viral RNA sequences at a ³H-DNA:³²P viral RNA molar ratio¹⁰ of 2.0. Cellular DNA was extracted from tissues and cell lines as described¹⁰. All DNAs were treated sonically so as to yield a mean size of 6–8S (the size of the ³H-DNA probes)¹⁰. DNA:DNA hybridisations were incubated at 65 °C in reaction mixtures containing 0.01 M Tris, pH 7.4, 0.75 M NaCl, 2×10^{-3} M EDTA, 0.05% sodium dodecyl sulphate, 30,000 to 40,000 c.p.m. of ³H-DNA and 2–4 mg of cellular DNA per ml. Hybridisations were started by heating the mixtures to 100 °C for 10 min, cooling on ice to 4 °C and incubating at 65 °C. At various times, 0.025 ml portions were removed and frozen at –80 °C until digested with the single-strand specific nuclease, S₁, as described²⁷. C_0t values (C_0 is the concentration of cellular DNA in mol l^{-1} and t is the time in s) were calculated as suggested by Britten and Kohne²⁸ as $(A_{260} \text{ ml}^{-1})/2 \times h$, and corrected to a monovalent cation concentration of 0.18 M (ref. 29). a, Annealing of RD-114 ³H-DNA probe to DNA extracted from: ○, domestic cat No. 3; ■, domestic cat No. 1; ●, F₁ hybrid No. 4; □, backcrossed kitten No. 1; ▲, a dog thymus cell line infected with RD-114, and ◆, leopard cat and backcrossed kitten No. 2. Comparable data were obtained with DNA probes prepared from the domestic cat type C virus, CCC^{2,3}, and with the FS-1 virus isolated from European wildcat cells³⁰. Δ, Self-association of non-repetitive domestic cat cellular DNA. ³H-thymidine-labelled domestic cat cellular DNA was isolated by removing the highly reiterated sequences that anneal by a C_0t of 800 (approximately 40% of the total DNA) by fractionation on hydroxyapatite¹⁰. This ³H-thymidine-labelled DNA (5×10^6 c.p.m. μg^{-1}) was then hybridised to total domestic cat cellular DNA. b, Annealing of FeLV ³H-DNA probes (Rickard strain)²² to DNA extracted from: ○, domestic cat No. 2; ■, domestic cat No. 1; ●, F₁ hybrid No. 3; □, backcrossed kitten No. 1; ▲, a dog thymus cell line infected with FeLV, and ◆, leopard cat and backcrossed kitten No. 2. Comparable data were obtained with the Gardner-Arnstein²³ strain of FeLV grown in a canine thymus cell line (FCf2Th). Δ, Self-association of unique sequence domestic cat cellular DNA. Domestic cat cellular DNA contains at least two distinct sets of RD-114-related sequences which are present in different reiteration frequencies. The F₁ hybrid and backcrossed kitten No. 1 have approximately half the number of copies of each set of related sequences. While only one set of virogyne sequences can be detected with the FeLV probe (Fig. 1b), the F₁ hybrid and backcrossed kitten No. 1 again are shown to contain half the number of copies as that found in the domestic cat parent.

lated sequences are located together at one (or relatively few) chromosomal sites.

The same cats were examined for FeLV-related genes using ³H-DNA probes prepared from various strains of FeLV^{22,23}. No cross-hybridisation between these probes and RD-114 is detectable^{15,24}. The results parallel exactly the data obtained with transcripts of RD-114 RNA. The domestic cat parent contains multiple copies of FeLV-related virogenes whereas the leopard cat parent lacks these sequences. The F₁ hybrids contain half the number of copies. Backcrossed kitten No. 1 has the same number of virogyne copies as its parent (the F₁ hybrid) although its littermate has no detectable sequences related to FeLV.

Table 1 summarises the hybridisation data; four clear classes of DNAs are evident. The first consists of animals that contain full complements of RD-114 and FeLV-related gene sequences. These cats contain both sets of virogyne sequences reiterated a comparable number of times, although there may be fewer FeLV-related copies. The animals in the second class, including all the F₁ hybrids and one of the backcrossed kittens, contain half the virogyne complement of the RD⁺, FL⁺ parents. A third class contains sequences that anneal to the viral probe with reassociation kinetics comparable with that seen for the association of the most slowly reannealing cellular DNA sequences and therefore probably contains one viral copy. This includes cloned heterologous cell lines producing high titres of either RD-114 or FeLV viruses. The fourth class completely lacks sequences related to either RD-114 or FeLV and includes the leopard cats and one of the backcrossed kittens.

If the multiple copies of RD-114 and FeLV-related sequences present in cat DNA had become physically separated from one another after their entry into the cat germ line⁹ they would not all have segregated together. The data rule out the possibility

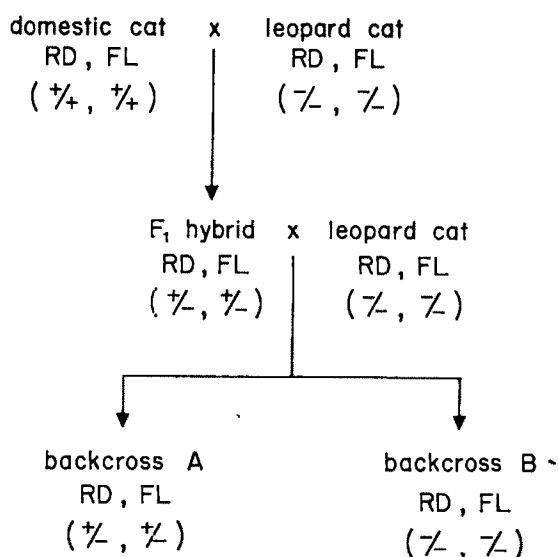

Fig. 2 RD-114 and FeLV type C viral genotypes of the various cats studied.

that each of the multiple copies of RD-114 or FeLV-related virogenes occurs on a different linkage group, as well as models of non-chromosomal inheritance of the multiple viral copies.

Since only certain *Felis* species contain RD-114 and FeLV-related sequences in their DNA, we propose that both classes of viruses were acquired by cats subsequent to their major radiation, most likely in the Pliocene, and that both sets of sequences have been perpetuated in the germ line^{9,18}. The multiple virogenes copies presumably arose as a result of gene duplication and/or unequal crossing-over after infection. The presence of multiple copies of both sets of virogenes in cat cellular DNA seems to be a general property of endogenous mammalian type C viruses; mouse, rat, hamster, pig and baboon DNAs also contain similar numbers of copies of their respective endogenous viruses¹⁹.

The genetic crosses described here provide a new approach to the study of the evolution of multiple gene systems. The virogenes sequences can be considered as one of the group of moderately repetitive sequences such as the genes for 5S RNA²⁵, histones²⁶ and feather keratin²⁰. The existence of natural populations of animals that either lack or contain DNA sequences related to both RD-114 and FeLV, and the ability of these cats to interbreed permits the study of the physiological and potentially pathological role of each of these genetically transmitted gene sequences. Hybrid animals containing half the number of virogenes copies and virogenes-negative cats should allow the study of the effects of gene dose on susceptibility and resistance to diseases mediated by both groups of type C viruses.

We thank J. Koci and G. L. Wilson for assistance, and R. Callahan and C. Sherr for comments and discussion. Supported in part by the Virus Cancer Program of the National Institutes of Health.

Identification of heat-dissociable RNA complexes in two porcine coronaviruses

THE coronavirus genome has been shown to comprise single-stranded RNA^{1,2}. Examination of the viral nucleic acid synthesised by pig kidney cells infected with transmissible gastroenteritis virus (TGEV) suggested that several molecular species, ranging in size between 18 and 28S, were involved in the viral replicative cycle³; similarly Tannock found a wide variation in the size of RNA molecules extracted from avian infectious bronchitis virus (IBV) by a phenol-sodium dodecyl sulphate (SDS) method². Extraction of IBV RNA by 1% SDS at 60 °C has, however, revealed a single component of molecular weight 9×10^6 corresponding to 60S by electrophoresis through 2.2% polyacrylamide gels⁴.

We have examined the RNA extracted from purified preparations of TGEV and a second porcine coronavirus—haemagglutinating encephalomyelitis virus (HEV)—and have found a 60-70S RNA component which dissociates into 35S and 4S material on heating above 60 °C in a way that closely resembles the genome of the oncogenic RNA viruses.

We had observed that treatment of purified TGEV with 1% SDS at 20 °C disrupted the virions and liberated a high molecular weight complex containing the RNA. On the assumption that this complex might comprise the hitherto undetected ribonucleoprotein, we extracted the material from TGEV preparations radioactively labelled with ³H-uridine or with ³H-leucine to determine which structural polypeptide was associated with the complex. As is shown in Fig. 1, however, the fast moving RNA complex has no detectable protein associated with it, while polyacrylamide gel analysis of the radioactivity remaining near the top of

Fig. 1 Rate zonal sedimentation of TGEV after treatment with 1% SDS at 20 °C. TGEV was grown in secondary pig thyroid cell (APT/2) cultures in the presence of 5-³H-uridine (○) or 4,5-³H-leucine (●) and purified by sucrose gradient centrifugation as described previously⁵. After treatment with 1% SDS at 20 °C for 15 min, each preparation was layered over a 6-ml 15-30% (w/w) sucrose gradient and centrifuged at 250,000g for 2 h in a swing-out rotor. The gradients were fractionated by siphon and total radioactivity was determined for each fraction.

the gradient demonstrated the presence of viral structural polypeptides⁵.

Extraction of RNA from ³H-uridine-labelled TGEV by 1% SDS at 20 °C followed by electrophoresis through gels containing 2% polyacrylamide and 0.6% agarose revealed a homogeneous band of high molecular weight RNA and a very small amount of radioactivity in the area of the marker dye, corresponding to approximately 4–7S (Fig. 2a). Similar extractions were performed on replicate virus samples using 1% SDS at 40, 60, 80 and 100 °C and the released RNA was electrophoresed as before. The electrophoretograms illustrated in Fig. b–e showed that the mobility of the major RNA band increased slightly as the extraction temperature was raised to 60 °C and, while the homogeneity of the leading edge of the band decreased somewhat, there was no obvious change in the 4S–7S region. As the temperature was increased through 80 to 100 °C, however, the radioactivity became associated with a broader band of RNA, whose mobility was at least twice that of the RNA extracted at lower temperatures, and there was an increase in the amount of RNA in the 4S region of the gel.

This apparent "melting" of the high molecular weight complex into smaller components with the liberation of 4S

Fig. 2 Gel electrophoresis of TGEV RNA following extraction in 1% SDS at various temperatures. TGEV was grown in APT/2 cultures in the presence of ³H-uridine and purified by sucrose gradient centrifugation. The preparation was suspended in L buffer (36 mM 2-amino-2-hydroxymethylpropane-1,3-diol (Tris); 30 mM NaH₂PO₄; 1 mM ethylenediaminetetraacetic acid (EDTA); pH 7.8) and SDS was added to 1% at 20 °C. The suspension was divided into five parts and each part was held in a water bath at 20 (a), 40 (b), 60 (c), 80 (d) or 100 °C (e) for 30 min. After cooling, sucrose was added to 5% (w/w) and bromophenol blue was added as a marker dye, each sample was layered over a 6 × 60 mm 2% (w/v) polyacrylamide/0.6% agarose gel⁶ and electrophoresed for 1 h at 8 mA per gel using L buffer containing 0.2% SDS. The gels were sliced into 1-mm fractions and the radioactivity of each slice was determined in a toluene-Triton X-100 scintillant. The location of the marker dye was estimated by eye and is represented by the arrows.

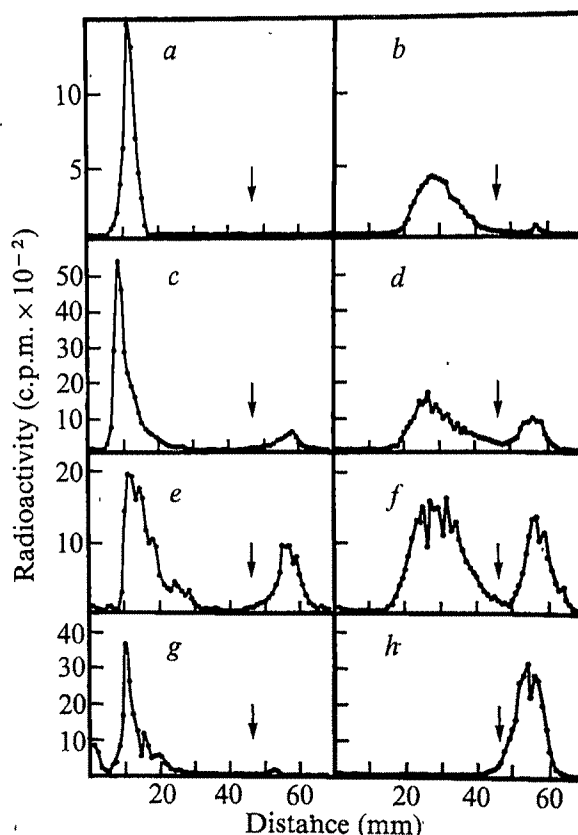

Fig. 3 Gel electrophoresis of RNA from RSV, TGEV, and HEV. TGEV and HEV were grown in APT/2 and primary pig kidney cell cultures respectively in medium containing ³H-uridine. Both viruses were purified by sucrose gradient centrifugation and suspended in L buffer. After 24 h at 4 °C or, in the case of the virus used in (g) and (h), after 20 d at 4 °C, SDS was added to 1% and the preparations were held at 20 or 100 °C for 30 min. Purified 60–70S RNA from RSV was held in 10 mM NaCl; 8 mM Tris; 7 mM NaH₂PO₄; 1 mM EDTA; 1% SDS; pH 7.8 at 20 and 100 °C for the same length of time. The preparations were cooled to 20 °C, sucrose and bromophenol blue were added and electrophoresis and fractionation were conducted as described for Fig. 2, using 6 × 70 mm gels. RSV RNA held at 20 (a), and 100 °C (b); TGEV extracted at 20 (c), and 100 °C (d) after 24 h at 4 °C; HEV extracted at 20 (e), and 100 °C (f) after 24 h at 4 °C; TGEV extracted at 20 (g) and 100 °C (h) after 20 d at 4 °C. The arrows denote the location of the marker dye.

RNA at temperatures above 60 °C closely resembles the findings for the oncogenic RNA viruses⁷. To determine the size of the coronaviral RNA components and their similarity to oncornaviral RNA, we compared the mobilities of RNA extracted from TGEV and HEV at 20 and 100 °C with those of purified Rous sarcoma virus (RSV) RNA held at the same temperatures. Figure 3a–f shows that, by this method, the RNA complexes extracted from the two coronaviruses are indistinguishable in size from the 60–70S component of RSV RNA and that, after heating, the TGEV and HEV RNA components are comparable in size to the RSV 35S RNA. There seems to be more heterogeneity in the coronaviral 35S RNA band than in the RSV equivalent and this holds true regardless of the time of the labelling period. Comparison of RNA extracted from TGEV labelled with ³H-uridine 0–4, 4–8, 8–12, 12–16 or 0–20 h after infection shows that, although the total radioactivity incorporated varied with the time of labelling period, the overall shape of the RNA curves after extraction at 20 and 100 °C were similar. This difference in heterogeneity may be due partly to the fact that we were comparing extracts from whole HEV and TGEV with purified 60–70S RNA from RSV, but it may also be caused by partial degradation of the RNA within the virion. That this undoubtedly occurs is demonstrated by the electrophoretograms illustrated in Fig. 3g–h, which were all derived

from TGEV that had been held at 4 °C for 20 d before extraction at 20 and 100 °C in 1% SDS. The 60–70S complex seems to be intact, but, on melting, the complex liberates only small fragments of RNA of approximately 4S (Fig. 3h). This suggests that the virus preparations have an associated ribonuclease capable of producing breaks in the 35S strand while they are complexed in the 60–70S form. Whether the large amount of 4S RNA detected in all HEV preparations so far examined (Fig. 3e–f) represents degraded viral RNA or host tRNA associated with the virions is not known.

Our inability to detect protein in the 60–70S RNA complex from TGEV does not exclude the possibility that there is a very small amount that is dissociating from the RNA at elevated temperatures in the presence of SDS. The similarity of behaviour and size between the coronaviral RNA and RSV RNA, together with the liberation of 4S RNA on melting suggests strongly that the TGEV and HEV 60–70S complex is held together by RNA–RNA interactions as is the RNA from oncornaviruses. We hope to characterise further the 60–70S complex and determine whether the viral 4S component is in fact host tRNA. Although the replication of these two groups of viruses is fundamentally different, the coronaviruses being entirely cytoplasmic in contrast to the essential nuclear phase of the oncornaviruses, a similarity in the structure of the genomes of the two groups raises interesting implications for the phylogeny of the RNA tumour viruses.

We thank Mrs Brenda V. Pike for assistance and Dr S. Martin, Imperial Cancer Research Fund Laboratories, London, for the gift of ³H-uridine-labelled RSV RNA. One of us (T.M.W.) was in receipt of a British Council Scholarship.

Presence of factor VIII-related antigen in blood platelets of patients with Von Willebrand's disease

VON WILLEBRAND'S disease (VWD) is an autosomally inherited disorder characterised by low factor VIII activity (antihaemophilic factor, AHF), prolonged bleeding time, reduced retention of platelets in a glass bead column and abnormal distocetin-induced platelet aggregation. The prolonged bleeding time in VWD has been attributed to the absence of a plasma factor, the von Willebrand factor (VWF), as shown by a correction of the bleeding time after infusion of normal and haemophilic plasmas¹. Addition of purified factor VIII *in vitro* specifically corrects the abnormal platelet retention and ristocetin aggregation in VWD^{2–5}, whereas transfusion of similar material into dogs with VWD also corrects the prolonged bleeding time (B.N.B., W. J. Dodds, J. A. van Mourik, J.J.S. and

W. P. Webster, unpublished). This led to the suggestion that factor VIII is closely related if not identical to VWF, although dissociation of factor VIII procoagulant activity from factor VIII-related antigen (F VIII-RA) is observed in certain conditions^{6,7}. The plasma concentration of F VIII-RA is usually reduced in VWD suggesting a reduced synthesis of factor VIII (VWF)⁸. In contrast to this we now report the presence of normal concentrations of F VIII-RA in platelets of patients with VWD. This F VIII-RA supported aggregation induced by ristocetin in a washed platelet system⁹, a property of factor VIII which has been attributed to VWF activity.

Human blood platelets were washed according to the method of Karparkin¹⁰. ACD-blood was centrifuged (10 min, 200g, 20 °C). Platelet rich plasma was diluted in 5 volumes of Krebs-Ringer buffer (pH 7.4) containing 9 mM Na₂-EDTA. After centrifugation (15 min, 1,000g, 4 °C), the platelets were washed once in Krebs-Ringer buffer containing 9 mM Na₂-EDTA and twice in Krebs-Ringer buffer containing 1 mM Na₂-EDTA. The platelet pellet was finally resuspended in Krebs-Ringer buffer containing 30 mM glucose and 1 mM ε-amino caproic acid. In the final washing fluid the protein content was lower than 50 μg ml⁻¹ (ref. 11), and the concentration of F VIII-RA, measured by electroimmunodiffusion was below 0.05 U ml⁻¹ (ref. 12). 1 U F VIII-RA was defined as the amount present in 1 ml pooled normal plasma prepared from 40 healthy subjects¹². In the final suspension (1 × 10⁶–3 × 10⁶ platelets μl⁻¹) the platelets were disrupted by freezing and thawing (four times) followed by centrifugation (60 min, 30,000g, 4 °C).

Ten suspensions of normal human platelets were tested. The concentration of F VIII-RA detected in the supernatant was 0.15 U mg⁻¹ platelet protein (range 0.11–0.25) or 43 U per 10¹¹ platelets (range 19–94). Expressed per platelet volume (8 × 10⁻¹⁵ l) (ref. 13) the concentration of F VIII-RA was 60 times (range 21–156) higher than that in plasma. Similar values were reported by Nachman and Jaffe¹⁴.

Platelet F VIII-RA showed a reaction of identity with plasma F VIII-RA, when tested in immunodiffusion using a rabbit anti-factor VIII serum and the antisera raised against the low ionic strength components (ref. 15 and B.N.B., J. van Mourik, S. de G., J.M.H.-H. and J.J.S., unpublished). Cross-immunoelectrophoretic analysis revealed an electrophoretic mobility comparable with that of plasma F VIII-RA.

Howard *et al.*¹⁶ quantitated F VIII-RA on intact washed normal platelets and concluded that F VIII-RA was firmly bound to the membrane fraction. A similar conclusion was reached by Bloom¹⁷ using an immunofluorescent technique. On the other hand, the localisation of F VIII-RA throughout the megakaryocytic cytoplasm is in agreement with its localisation inside the platelet¹⁸. Nachman and Jaffe¹⁴ reported the presence of F VIII-RA in subcellular membrane and granula fractions. We examined this localisation by a previously described indirect immunofluorescent technique^{19,20}. Suspensions of intact washed platelets were incubated with antifactor VIII in suspension, washed again, and incubated with fluorescein isothiocyanate labelled horse anti-rabbit globulin (Central Laboratory of the Netherlands Red Cross Blood Transfusion Service, Amsterdam). A drop of this suspension was studied under the fluorescence microscope. Most platelets were unstained, whereas a vivid granular staining was obtained after disruption of membranes by air drying of a drop of the same platelet suspension on a glass slide. The specificity tests have been described in detail elsewhere²⁰. Staining with normal rabbit serum instead of with antifactor VIII was used as a control. The difference between staining in suspension or staining after air drying suggests that F VIII-RA is present inside the platelets.

In agreement with the results of Howard¹⁶ and Nachman and Jaffe¹⁴ no factor VIII activity could be detected in

Fig. 1 Chromatography of a platelet lysate obtained from a patient with VWD. A column (K15/30, Pharmacia, Uppsala) was packed to a gel height of 24 cm with Sepharose 6B (Pharmacia, Uppsala) and equilibrated with a barbitol-saline buffer (0.0167 M barbitol, 0.125 M NaCl, pH 7.0) containing 3.3% dextran (Rheomacrodex, molecular weight 43,900, Pharmacia AB) and 1 mM ϵ -amino caproic acid. Platelet lysate obtained from 70 ml of normal human blood or blood from patients with VWD in a final volume of 1–2 ml was applied to the top of the column and the column was eluted with buffer at 15 ml h⁻¹. All procedures were performed at 4 °C. Fractions were analysed for: (1) absorbance at 280 nm (—○—); (2) F VIII-RA as measured by Laurell technique (○)¹²; (3) fibrinogen as measured by Laurell technique (●)²⁷; and (4) presence of VWF activity as determined by support of ristocetin aggregation in washed platelet suspensions (▲—▲)⁹.

the supernatant of platelet lysates. It should be noted, however, that a clot-promoting activity was detected using a one stage factor VIII assay²¹. This clot-promoting activity could not be inhibited by human circulating factor VIII inhibitors, and was also detected in the supernatant of lysed haemophilic platelets. The clot promoting activity was therefore not attributed to factor VIII and probably resulted from tissue factor activity released by contaminating leukocytes. The lack of factor VIII activity could not be attributed to the freezing and thawing procedure, because factor VIII activity was already absent after the first freeze-thaw manipulation. The presence of proteolytic enzymes, as a cause of the decreased factor VIII activity is more difficult to exclude. However, addition of 1 mM ϵ -amino caproic acid or other proteolytic inhibitors (benzamidine, 1 mM; Soya bean trypsin inhibitor, 0.02 mg ml⁻¹; and phenyl methyl sulphanyl fluoride, 1 mM) to the final washing fluid before disruption of the platelets had no effect on the measurement of factor VIII activity. Moreover the supernatant obtained after freezing and thawing did not inactivate the clot promoting activity of purified factor VIII during 24 h of incubation at 37 °C. This indicates that the factor VIII identified in platelets as F VIII-RA is biologically inactive. Similar observations were made for human endothelial cells, FVIII-RA was present¹⁸ but devoid of factor VIII activity²².

The presence of F VIII-RA has been demonstrated with haemostatic plugs²⁰. Electron microscopic observations of haemostatic plugs in rabbits and dogs have shown that the platelets are mostly degranulated²³. In preliminary investigations we found that collagen as well as thrombin (final concentration 5 U ml⁻¹, Roche, Basle) produced little or no release of F VIII-RA from intact platelets which explains the presence of F VIII-RA in haemostatic plugs that had undergone release.

Normal concentrations of F VIII-RA were detected in platelets from patients with haemophilia A. F VIII-RA was also measured in platelets from 15 patients with VWD (Table 1). All patients except No. 10, who was considered to manifest VWD type II (ref. 24), had low or absent

F VIII-RA in their plasma and fulfilled the criteria of VWD. In two patients (Nos 4 and 11) no F VIII-RA was detected in the platelets, whereas all other patients had normal concentrations of F VIII-RA in their platelets. These results were supported with an indirect immunofluorescence technique¹⁹ applied to drops of platelet suspensions air-dried on a glass slide. A positive result was obtained with all patients, except one (No. 4) of the two patients without F VIII-RA in their platelets. The other patient was not tested. It is of interest that the patient (No. 11) without F VIII-RA in his platelets is a brother of patient No. 15, suggesting that the absence of F VIII-RA in platelets of patients with VWD is not hereditary.

F VIII-RA from normal human platelets was purified by gel chromatography according to van Mourik and Mochtar²⁶ (Fig. 1). Both F VIII-RA and VWF-activity were detected in the void volume (V₀) fractions from these columns, which is in agreement with observations for plasma factor VIII². Figure 1 shows the results for the chromatogram lysates of VWD platelets. In 3 experiments, the V₀ fractions contained both F VIII-RA and VWF-activity, whereas no VWF-activity and F VIII-RA was detected in the V₀ of VWD platelet lysates containing no F VIII-RA.

These results indicate that although F VIII-RA is reduced or absent in the plasma of VWD patients, F VIII-RA can be detected in the platelets of most of these patients.

Two reports in the literature are in conflict with our results. Howard *et al.*¹⁶ failed to demonstrate any F VIII-RA in the platelets of one patient with severe VWD and Coller *et al.*²⁸ found platelets from two patients to be negative in immunofluorescence studies. Shearn *et al.*²⁹, however, comparing five different heterologous antifactor VIII antisera found that the platelets from one patient with severe VWD were positive with four of the five antisera using an immunofluorescence technique. The presence of the antigen was also demonstrated by cross immunoelectrophoresis. It should be noted that these studies were performed with a very limited number of patients, whereas the techniques used also differ from ours. One explanation for the discrepant results, may be contamination of the antifactor VIII sera

Table 1 Platelet factor VIII-related antigen (F VIII-RA) in VWD

Patient	FVIII-RA/mg platelet protein (U)	FVIII-RA/10 ¹¹ platelets (U)	FVIII activity plasma (U ml ⁻¹)	FVIII-RA plasma (U ml ⁻¹)	Bleeding time ²⁵ (min)

with antibodies produced in rabbits against platelet fragments, which may be carried along in the purification of factor VIII. The following observations suggest that in our experiments the antigen detected by rabbit anti-factor VIII in platelets is indeed F VIII-RA.

(1) The platelet antigen could not be distinguished from plasma factor VIII when tested in immunodiffusion and cross immunoelectrophoresis, using antifactor VIII and the antisera against the low ionic strength components of factor VIII. (2) The positive immunofluorescence of haemostatic plugs was completely blocked by absorption of antifactor VIII with purified factor VIII, the characteristics of which have been described in detail^{15,26}. (3) In preliminary experiments antibodies were prepared against normal and VWD platelet F VIII-RA. These antisera precipitated with purified factor VIII when tested in immunodiffusion experiments.

Previously it has been suggested that the capacity to synthesise F VIII-RA is reduced in VWD. This was concluded from the fact that F VIII-RA is reduced or absent in plasma of patients with VWD. Our findings, however, suggest that the platelets, or more likely the megakaryocytes retain the capacity to synthesise F VIII-RA. Another possible explanation for the presence of F VIII-RA in VWD platelets is that the platelets selectively sequester F VIII-RA from an extracellular source such as plasma or endothelial cells. The fact that F VIII-RA from normal as well as from VWD platelets supports ristocetin-induced aggregation may indicate that platelet F VIII-RA is also identical to VWF. VWF has been deemed necessary for normal haemostasis because patients with VWD who lack this factor have a prolonged bleeding time. The presence of F VIII-RA in haemostatic plugs²⁰, and blood platelets suggests that it serves some useful function in haemostasis. A direct haemostatic role of platelet F VIII-RA seems unlikely because it is not released from intact platelets and is present in platelets of patients with VWD who have prolonged bleeding times. Although plasma F VIII-RA seems to be more important in haemostatic plug formation the presence and synthesis of F VIII-RA in endothelial cells and its localisation in blood platelets suggest additional haemostatic functions for this molecule.

We thank Dr Jean Dodds for criticising this manuscript. This investigation was supported in part by the Foundation for Medical Research (Fungo) which is subsidised by the Netherlands Organization for the Advancement of Pure Research (ZWO).

Corrigendum

In the article "The origin of nuclei and of eukaryotic cells" by T. Cavalier-Smith (*Nature*, **256**, 463; 1975) the two unlabelled arrows at the top right of Fig. 5 should read (from the top) Prasinophyta and Charophyta, respectively.

Erratum

In the article by B. Donzel and M. Goodman (*Nature*, **256**, 750; 1975) the title should have read "Synthesis and conformations of hypothalamic hormone releasing factors: two TRF analogues containing backbone N-methyl groups" and not as printed.

matters arising

Strainmeter technology

WE agree with Sydenham¹ that many problems remain to be investigated with strainmeters and that many results obtained so far are ambiguous or contradictory. Measurements of strain (especially long period strain) are beset by a host of problems not found in such areas as magnetometry, so it may, therefore, be unreasonable to expect strainmeters to be as simple as magnetometers. Further, it may be time to opt for a smaller number of higher performance instruments and to reconsider the continued deployment of more and more strainmeters in a given area.

Although the measurement of strain is in principle differential, in practice the long term nature of most strain measurements requires great stability in the reference length, the realisation of which is tantamount to constructing a length standard.

Conventional materials, such as fused silica, have coefficients of expansion of about $10^{-6} \text{ }^{\circ}\text{C}^{-1}$ so that thermal fluctuations must be held to less than $10^{-4} \text{ }^{\circ}\text{C}$ over the entire length of the instrument if the thermally induced strain signal is to be kept below 10^{-10} (in order to measure a particular component of the Earth tides to an accuracy of 1%, for example).

Sydenham has shown³ that this can be done for very short strainmeters (10 m) in the laboratory. The ancillary apparatus required to achieve microdegree stabilities is, however, far from simple, even for 10-m instruments, and difficulties in stabilising longer instruments can be expected to increase more than linearly with length.

The length of fused silica strainmeters also depends on the ambient humidity in a nonlinear manner (F. Homuth, unpublished thesis). Thus, stabilisation of the humidity is also required. That could be accomplished, at least to the first order, by enclosing the instrument in an evacuated pipe, in which case, of course, it would look exactly like a laser strainmeter.

By way of contrast, saturated absorption stabilisers routinely achieve stabilities and reproducibilities of 10^{-11} or better without any sort of thermal or environmental isolation. These data on stability and reproducibility are obtained by direct comparison between two independently stabilised devices.

It is true that the interferometer comprising the heart of the laser strainmeter is sensitive to fluctuations in atmospheric pressure and temperature, the fractional

change in the optical path length being 2×10^{-10} per mtorr. A simple mechanical pump can easily evacuate the interferometer to a few mtorr and can maintain the pressure at that level indefinitely. The temperature dependence of the index of refraction at a few mtorr is negligible.

Until the advent of saturated absorption stabilisers, attempts to measure long term strain accumulations with conventional strainmeters were severely limited by the signals produced by various environmental effects. There is no question that conventional strainmeters can be used for conventional seismology and even for normal mode work (periods of less than about 1 h). In fact, many of the best normal mode data come from quartz rod strainmeters⁴. But for periods of longer than 1 h it becomes more and more difficult to isolate adequately the reference length.

Thus, our conclusions are quite different from those of Sydenham. We feel that there is no 'best' overall strainmeter, and that each instrument has advantages and shortcomings.

Laser strainmeters are usually faulted for their high cost and low reliability. But neither the cost nor the sophistication of a laser instrument increases very much with length, so that long instruments are quite a bit cheaper per metre than are short ones. We suggest that the opposite may be true for instruments requiring good thermal stability over their entire length. If, as Homuth (unpublished) suggests, stabilisation of the ambient humidity turns out also to be necessary, the cost of the total system will be even higher, and the reliability, presumably, lower.

SYDENHAM¹ has failed to appreciate that problems exist in studies of Earth strain which will not be solved by producing the 'ultimate' strainmeter. Strain signals cover a wide frequency range, and signal sources and noise vary across the spectrum. The correct way to assess instrument performance is to examine noise levels as a function of frequency (see ref. 2, for example). An early invar wire strainmeter

designed and constructed by Sydenham³ achieved signal-to-noise ratios of up to 100 on tidal peaks and although the instrument had defects, a poor signal-to-noise ratio was not the most important. As Sydenham has never published any power spectra it is not possible for others to compare the behaviour of their instruments with his. His interest in drift and stability amounts to an avid concern with only the lowest frequencies of the spectrum. Using drift as a criterion for comparison, however, it is interesting to note that Sydenham's early instrument has exhibited less long term drift than he now claims for quartz instruments⁴ although even that level is too high to permit a strainmeter to compare in the long term (more than 1 yr?) with geodetic techniques for determining secular strain.

Sydenham's discussion of tensor arrays is also misleading. Given six instruments and a good site, a tensor array will not usually give maximum useful information. Geophysically important results (different examples are given in refs 5–9) can be obtained using single instruments or linear arrays of horizontal strainmeters and these also reveal site effects^{7,10,11}. Should a site prove to be badly chosen perhaps it is best to go elsewhere.

No published data suggest that mechanical strainmeters are universally better than optical strainmeters (or vice versa). We register surprise that since Sydenham favours borehole instruments he makes no comment on the borehole dilatometer developed at the Carnegie Institution, Washington¹² or the 'Geotech' borehole strainmeter¹³.

SYDENHAM REPLIES—My paper was compiled in late 1973, and represents events of that time. A vital word—'headed'—did not appear at the end of the title as intended.

By early 1974, experimental Earth-strain research had reached a stage at which mechanical instrumentation was no longer a significant unknown of any programme. The next stage in maturity was to know how to obtain geophysical contributions with the hardware. In 1974, the modifying effects of cavities and regional topography were universally recognised and serious studies were initiated (earlier work with linear arrays was simplistic and often non-productive). Important and unexpected results have emerged from this approach (ref. 1 and D. P. Blair, unpublished thesis) showing how and to what extent expected strain magnitude is altered. Blair (unpublished), extending Harrison's¹ finite-element work from two into three dimensions has found that topography selectively alters the amplitudes of the tidal spectral components. This result apparently explains that topography was the influencing parameter sought without success at the Queensbury site²; yet King questions my earlier predictions of the relevance of a tensor study.

Reference about strain-creep using linear arrays was indeed omitted as it is more usually studied using quite coarse instruments (though in my original manuscript it was suggested that creep theory, as studied by materials scientists, could be relevant to an understanding of creep mechanisms). This concept has since been invoked³.

I suggested that theory might help reduce the number of components needed to understand how strains relate at different places. Available techniques now allow the prediction of site effects using only a geological map, a topographical map and computing ability. We can now eliminate most known causes of incompatibility between theory and practice, leaving the interesting differences to be investigated. Deep-sea cotidal charts, for instance, might soon be updated using corrected Earth-strain data (D. P. Blair, unpublished thesis). Resolution of the interval argument could be near: structural studies based on topographical studies should give quantitative guidelines.

My work on drift reduction in instruments led to the development of the mechanical instruments King's group now uses. A very real advantage of high stability is the ease it offers of transducer design and recording. Quartz chain catenary instruments need no autoranging recorder nor any adjustments over yearly periods. Long-period differential drift

between two different quartz instruments is no greater than 5 parts in 10^{12} per hour⁴. Very long baseline interferometers excepted, no available geodetic technique can provide drift as low.

Frequency spectra could provide a means of assessing instrument performance but only if the power contributions of the Earth and the instrument can be distinguished separately. I have seen no point in publishing the tidal spectra for they contribute little. The work of Berger and Levine⁵ referred to by King represents excellent spectral analysis, but does it provide useful knowledge? If a site topography alters the amplitude¹ and composition of signal (ref. 1 and D. P. Blair, unpublished thesis) it does likewise to the tensor fluctuation, noise. Comparisons could be out by a factor of 0-3 if site coefficients differ greatly.

Is not the ultimate strainmeter one that provides adequate quality data, ease of recording, ability to be used anywhere in any direction, is the cheapest, the quickest to install, creates the smallest cavity error, automatically compensates for any local thermoelastic effect, and gives high reliability? A core-hole instrument (D. Curtis and P. H. S., unpublished) offers that at the economic ratio of 150 to one (compared with the first kilometre-length surface laser instrument). Until laser instruments reveal significant geophysical information not gained by well designed, mechanical equivalent extensometers, I cannot see how it can be argued that they are worthwhile geophysical tools. Surely, Levine does not justify laser expenditure on cost per unit length at this stage of uncertainty about the ideal interval?

Levine's comments on environmental effects on quartz can be misleading. Ambient control in subsurface installations is usually just within needs. Even if quartz is unstable with humidity change, it is easy to control relative humidity with a passive flexible enclosure.

The cost of advanced total environmental control⁶ is no more than that of a supplying and running a fail-safe evacuated enclosure. I again stress the point, however, that this line of reasoning is not fundamentally correct. An instrument having the same thermal coefficient (made of stainless steel, not quartz) as the host rock in which it is buried, requires no ambient compensation.

Extinction of taxa and Van Valen's law

VAN VALEN¹ has proposed an evolutionary-law that has attracted considerable attention²⁻⁶. He showed that plots of survivorship of taxa as a function of age are commonly log-linear (see Fig. 1 of ref. 1). This he interpreted to mean that the probability of extinction of a taxon is independent of its age, and thus formulated the law: "The effective environment of the members of any homogeneous group of organisms deteriorates at a stochastically constant rate."¹ We show here that survivorship analysis of the log-linear curves constructed by Van Valen does not warrant the interpretation that he assigned to it; support for Van Valen's law must be sought elsewhere.

In life table analysis one of two methods are used to construct a survivorship curve⁷⁻⁹. Horizontal, dynamic, or cohort life tables require a set of optimisms of even age (usually taken at birth), whose survivorship curve is derived from a complete analysis of the timing of deaths. All that is required is to record the age of death of each member and plot the number of survivors for each age class. Vertical, static, or actuarial life tables differ in that a sample of living organisms (or of ageable remains of dead organisms) is collected over a series of ages¹⁰. The critical assumption of the vertical life table is that the proportion of organisms within each age class decreases as a function of the age-specific death rate.

Van Valen claimed that his data were compiled in cohort-type tables, but Raup⁵ has argued that Van Valen used vertical life tables for extinct taxa. In fact, Van Valen combined the two types of life table analysis for both living and extinct taxa. The abscissa of his plots for extinct taxa is time of survival, arranged in such a way that all taxa are scaled as if they had originated simultaneously. For living taxa his abscissa scaling procedure is a straightforward reversal of the procedure for extinct taxa, since all living taxa are contemporary but evolved at various times in the past. In both cases the data seem to form a cohort, but they clearly do not. In the case of extinct taxa the scaling procedure is entirely responsible for the appearance of a cohort, but since the actual times of origin of all points are not the same, there can be no cohort analogous to an ecological life table. In reality the data constitute a vertical life table plotted to appear as a cohort, giving a survivorship curve without additional calculations. In the case of living taxa the data form a reversed cohort table, enabling survivorship to be estimated

directly, assuming that such a reversed table is meaningful.

Van Valen's graphical analysis does not contain the usual interpretation of survivorship probabilities. Ordinary survivorship analysis is specific for a particular sample of organisms over a short time interval and a reasonably constant environment. Thus, analysis of survivorship and mortality reveals patterns of life history in relation to some set of environmental (biotic and abiotic) interactions. This is why log-linear survivorship curves of any kind of organisms are rare, since log-linear curves imply that all members have an equal chance of dying regardless of age. Van Valen's plots are fundamentally different. The time scale is in tens of millions of years, but environmental conditions have not been anything near constant over such long time spans¹¹. Furthermore, members of the 'population' (the set of data points) do not necessarily share many common characteristics. They are hardly a homogeneous group reacting to a set of environmental conditions in the same way; they do not necessarily coexist or even share similar environments. Van Valen's survivorship curves aggregate greatly both the time-age scale and environmental conditions.

Given the scaling used by Van Valen, log-linearity is to be expected regardless of whether the probability of extinction of a taxon is or is not independent of age. Four levels of aggregation contribute to the appearance of log-linearity. (1) The environment-taxa relationship is lost by using taxa that have existed in different places at different times and aggregating them into the analogy of a population; environmental variations over time and space are effectively eliminated. (2) The long time scale ensures that nonlinearity could result only from extraordinary irregularities in extinction rates lasting for epochs. Even major waves of extinctions such as occurred at the Permian-Triassic and Cretaceous-Tertiary boundaries are reduced to small irregularities in the curves. (3) Elimination of points from both ends of the curves (representing taxa of relative short existences and those surviving for very long periods) reinforces linearity. Raup⁵ has already made this argument effectively. (4) The use of high order taxa rather than lower level taxa (ideally, species) makes the data points insensitive to variation among taxa and among the environments.

Because of their high level of aggregation, Van Valen's curves effectively eliminate all but the most extraordinary events, that is, they are relatively insensitive to perturbation. It is the aggregated scale itself which is responsible for log-linearity. The inclusion of

stochastic events to explain variation then requires a very broad definition of 'stochastic'.

At least three different questions must be distinguished in discussions about extinction probabilities. One question is whether the probability of survival of a taxon or group of taxa is the same at all geological times. This question must be answered in the negative—the fossil record shows that during periods such as the Permian-Triassic boundary any existing taxon had, on the average, a greater probability of becoming extinct than at other geological time. A second question is whether, at any given geological time, the probability of extinction is the same for all taxa of a given group. The answer to this question is likely to be also in the negative—at any given time, different related taxa may have different probabilities of becoming extinct. The third question is whether at any given geological time, the probability of extinction for any one taxon is independent of its age. Evolutionary theory predicts an affirmative answer to this third question. Natural selection promotes adaptation to the current environments of a species but does not anticipate the future. Confirmation of this prediction must await further studies.

VAN VALEN REPLIES—Foin, Valentine and Ayala¹ have produced a curious mixture of misinterpretation and conceptual confusion. I was careful² to avoid saying that 'the probability of extinction of a taxon is independent of its age'. This is true only for the mean probability (propensity) for a set of taxa, and I gave reasons³ for believing that individual taxa do often have different probabilities at different ages.

The reasons derive from both evidence and conventional theory, which therefore does not predict constancy as Foin *et al.* claim. Some subtaxa, for example those that are widespread and that contain many species, do have a low probability of extinction, as expected. Together with the observed mean constancy, this requires that the distribution of probabilities of extinction itself be regulated over time², so that the mean probability for older taxa is the same as that for younger ones. Some taxa therefore become more susceptible with age.

The critics seem not to have heard of composite life tables, which are a standard type³⁻⁵. In this type the data are asynchronous and must usually be analysed by the dynamic method. Simpson⁶ first made composite life tables of taxa from the fossil record. Raup⁷ did not, as claimed, make the elementary mistake of believing I treated extinct taxa by vertical analysis, although I disagree with part of what he did say.

One of the few advantages in using the fossil record for biological analysis is its averaging effect⁸. Local spatio-temporal peculiarities are indeed averaged out. This enables general properties to reveal themselves while 'noise' is minimised.

Any realistic combination of taxa with different characteristic probabilities of extinction gives a concave curve (convex in the terminology of analysis). The fact that the curves are rarely concave (and then only for groups with other evidence of heterogeneity, for which the same subgroups are found as for survivorship analysis) implies that the mean probability is roughly constant over long intervals. There are many causes of the various small irregularities in the curves (ref. 2 and L.V.V., unpublished). Low stratigraphic resolution makes the upper left extreme of the curves unreliable, and the low numbers of taxa at the bottom of a log scale make exceptions at the lower right extreme, even when real, of little importance. Appreciable nonlinearity is nevertheless easily detectable: I have in fact detected ostensible exceptions in both directions⁹, which do not affect the interpretation of a long term constancy.

Foin *et al.* have a somewhat subtle confusion reminiscent of the denial¹⁰ of a long term constancy in protein evolutionary rates. In neither case will "capricious" factors¹⁰, even acting over a long time, give the observed similarity in mean rate for different long intervals. They give a quasi-random walk of rates that is unconstrained by any predictable controlling distribution and so diverges wildly. Even an ordinary Markovian random walk usually diverges and so would usually

give a nonlinear curve. The observed degree of similarity can occur only by the existence of feedback control on a single mean value that is stable over long intervals¹¹ in spite of 'random' perturbations, and it is the very existence of this regulated mean which is the most interesting aspect of both kinds of phenomena.

The claim that I didn't use "lower level taxa (ideally, species)" is strange. I used all available and adequate data: 5 graphs were for species, 34 for genera, and 17 for families. The evidence of constancy is similar for each category. Because supraspecific taxa have different numbers of species, their observed linearity is evidence² for the ecological reality of supraspecific taxa.

I gave the first demonstration² that the mean probability of extinction (and that of branching) of subtaxa of a higher taxon varies in geological time. All previous studies had confounded either the absolute number of subtaxa, or the length of geological periods, with this probability. I also gave evidence that there is real heterogeneity in the probability of extinction of contemporaneous subtaxa.

Here is an apparent paradox: individual subtaxa vary both contemporaneously and over time in their susceptibility to extinction, and the mean susceptibility varies over time, yet the mean is constant over long intervals. The Red Queen's Hypothesis^{2,11,12} attempts to resolve the paradox by treating evolution as mostly ecologically rather than genically controlled, and as a zero-sum game of a kind which game theory has ignored. (In response to an earlier discussion¹³ what else is needed for the resolution is simply an independent maintenance of taxonomic diversity, which is an empirical fact whatever its detailed explanation.) As a by-product this ecologically selectionist theory explains the major features of molecular evolution at least as well as the genically neutralist and genically selectionist theories. Some of these congruences have been published¹¹, and I have found that one of the two apparent difficulties¹¹ of the hypothesis does not exist when explicitly tested¹⁴.

University of Chicago

Sodium flux, action potential and temperature dependence

LANDOWNE¹ and Cohen and Landowne² reported that extra Na flux during the action potential in squid axons increased little with decreasing temperature, the overall experimental Q_{10} being about 1/1.4. Hodgkin and Huxley³, however, computed a Q_{10} of 1/2.87 by assuming that temperature affected only the rate constants governing ion permeability changes. This discrepancy between experiment and theory was interpreted^{1,2} as indicating that nerve membranes do not function by changes in ion permeability⁴. We have used Hodgkin-Huxley-type equations³ and incorporated experimental temperature dependencies of the maximum possible Na and K conductances (\bar{g}_{Na} and \bar{g}_K) and the nonspecific leak conductance (g_L). Our results seem largely to resolve the discrepancy. A similar resolution of discrepancies between measured and computed K fluxes was proposed by FitzHugh and Cole⁵.

Membrane action potentials were computed with Hodgkin-Huxley equations, modified for *Myxicola*⁶, using a modified fourth-order Runge-Kutta algorithm, and the six-parameter model⁶ (without reference to inactivation parameters determined with conditioning pulses). Q_{10} s of the parameters, from Schauf's results with *Myxicola*⁷, are: 2.64 for Na activation rate constants (α_m and β_m), 2.56 for Na inactivation rate constants (α_h and β_h), 3.02 for K activation rate constants (α_n and β_n), 1.37 for \bar{g}_{Na} , 1.50 for \bar{g}_K , and 1.34 for g_L . We used these equations because good temperature data were available. We regard them only as an empirical description of the action potential.

Figure 1a and b shows action potentials and the time courses of the Na currents, computed at 5 °C and 15 °C. Table 1 shows temperature effects on time to rise, time to decline, and duration at +50 mV of the action potential. The Q_{10} of the duration at +50 mV (1/2.75) agrees well with the experimental value⁷ of $1/2.47 \pm 0.2$. Also shown are values for net Na movement during the action potential, (pmol cm⁻²) obtained by integrating the Na current curves of Fig. 1a. Taking the Q_{10} of the net Na entry as a measure of the Q_{10} of the extra Na flux, we get 1/1.82 which agrees reasonably well with the experimental value (1/1.4), considering that the preparations differed

and we simulated single membrane action potentials, not repetitive propagated responses. Computations made excluding the temperature dependency of \bar{g}_{Na} , \bar{g}_K and g_L gave a Q_{10} of 1/2.44, much as Hodgkin and Huxley³ reported and divergent from the experiments.

We find, therefore, no serious discrepancy between the measured temperature dependency of the extra Na flux during an action potential and that computed

Fig. 1 a, Two computed *Myxicola* action potentials, at the temperatures indicated. Computations have been made according to the six-parameter model of Goldman and Schauf⁶. The experimental temperature dependencies of \bar{g}_{Na} , \bar{g}_K and g_L , as well as those of the rate constants governing the ion permeability changes have been included. b, Computed time course of the Na currents for the two computed action potentials (a)

from Hodgkin-Huxley kinetics and so major conclusions on the mechanism of ion translocation do not seem warranted. This agrees with reports of a close correspondence between net Na flux determined from voltage clamped currents and

Table 1 Computed temperature effects on the action potential in *Myxicola*

	Time from +25 mV to peak (ms)	Time from peak to 0 mV (ms)	Duration at +50 mV (ms)	Net Na movement (pmol cm ⁻²)
5 °C	0.85	4.38	2.75	5.13
15 °C	0.44	1.73	1.00	2.82
Q_{10}	1/1.93	1/2.54	1/2.75	1/1.82

LANDOWNE AND COHEN REPLY—Goldman *et al.*¹ state that they find no serious discrepancy between the measured temperature dependence of the extra sodium flux during an action potential and that computed from Hodgkin-Huxley kinetics.

We have discussed² this discrepancy, or the lack thereof, in a qualitative fashion and both we² and Fitzhugh and Cole³ concluded that there is still a discrepancy even when the effect of temperature on the maximum conductances was included. Although Hodgkin and Huxley succeeded in predicting the electrical behaviour of the axon membrane based on their measurements of currents resulting from potential steps, they noted that at room temperature there was disagreement between the computed ion fluxes and those found experimentally⁴. We have also computed the fluxes predicted by the Hodgkin-Huxley equations and find there is considerable disagreement with experimental data at many temperatures.

The Hodgkin-Huxley equations were solved every three degrees from 3 to 27 °C and the calculated extra unidirectional tracer fluxes for membrane action potentials are shown as the solid curves in Fig. 1, together with the experimental data. Curve 1 represents the fluxes predicted by the unmodified Hodgkin-Huxley equations with a Q_{10} of 3.0 on the rate constants and 1.0 on the conductances. These calculated fluxes are within 1% of those given in Table 5 of Hodgkin and Huxley's original calculations at 6.3 and 18.5 °C (ref. 4). Curve 2 shows the effect of including a Q_{10} of 1.5 on the conductances and curve 3 was generated by using the Q_{10} s given by Goldman *et al.*¹. By taking the ratio of the net fluxes at 5 and 15 °C from the calculations for curve 3, a Q_{10} of 1.8 is obtained, similar to that of Goldman *et al.*¹. Clearly, none

of the curves fits the experimental data very well although, as suggested previously^{2,3} and by Goldman *et al.*¹, the fit is improved by including the effect of temperature on the maximum conductances. All the computed action potentials look qualitatively similar to experimental action potentials. Thus it seems that the appearance of the computed action potentials is not a good criterion for prediction of the appropriate fluxes.

The experimentally observed Q_{10} s were 1/1.4, 1/0.7 and 1/1.6 for the extra Na influx and 1/1.0, 1/1.3 and 1/1.2 for the extra Na efflux, for a variety of experimental conditions. We think that it is quite possible that these numbers are smaller than 1/1.8.

Equivalence principle

BOTH Bishop and Landsberg¹ and Kilminster in his review² use the argument

Gravitational redshift

→ Retardation of clocks

→ Space-time curvature

where we have identified the "non-Minkowskian metric"¹ and the phrase "the geometry of space-time is modified"² with space-time curvature. We have shown³ this argument (which is due to Schild^{4,5}) to be invalid and gave the rather obvious counterexample of a uniform gravitational field where space-time is flat (since the Riemann curvature tensor vanishes).

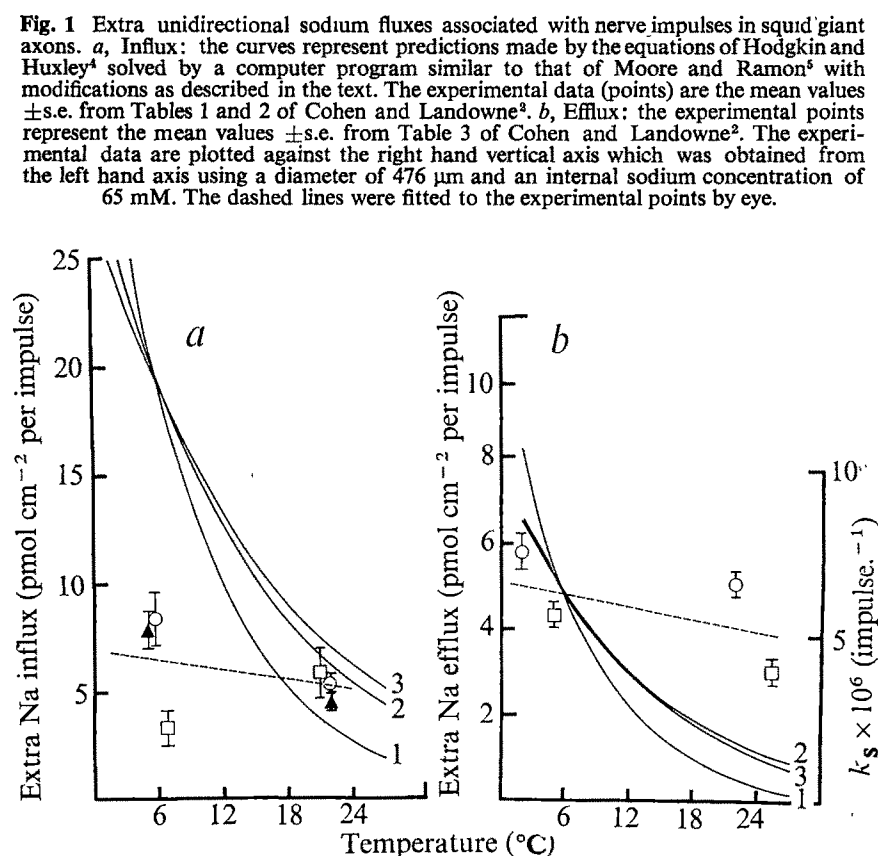

Einstein's 1911 paper is not, of course, in the framework of Newtonian physics. The argument

Equivalence principle

→ Retardation of clocks

cannot be applied in Newtonian physics because of the existence of an absolute time. The principle of equivalence itself is only partly contained in Newtonian physics in that "fictitious forces" can be equated with gravitational forces. Since the equivalence principle requires, in addition, that the behaviour of clocks under the influence of a gravitational field and an (locally equivalent) acceleration field be indistinguishable at a point, it may not be fully incorporated into Newtonian physics.

The redshift which arises in the treat-

ment of accelerated motion requires only the use of the Doppler effect and is merely equivalent to the statement of conservation of energy⁵. Only in special relativity can one equate a Doppler shift with clock retardation which is necessary so that all inertial observers measure the same value for the velocity of light. The principle of equivalence extends this to all freely falling observers.

Furthermore, it can be argued that the full principle of equivalence would be inconceivable before the advent of special relativity: as long as one believed that the velocity of light depends on the motion of the source and/or of the observer, how could one equate an accelerated system with one at rest but in a gravitational field?

We agree with Bishop and Landsberg that relationships between inertial and non-inertial frames are not suitable for discussing the gravitational redshift, and, in fact, this lies at the basis of our treatment in ref. 3.

⁵ Misner, C. W., Thorne, K. S., and Wheeler, J. A., *Gravitation*, 187 (Freeman, San Francisco, 1973).

As one of the authors referred to by Bishop and Landsberg¹, I would like to comment before students abandon their text books. Bishop and Landsberg¹ recommend that one should not use Newtonian mechanics with the principle of equivalence, to develop the gravitational redshift. They say that the result "is an absurd conclusion, since Newtonian physics operates with an absolute time". The principle of equivalence also leads to the result that the path of light is curved in a gravitational field. Thus, in another context, it is equally absurd to use the principle of equivalence with special relativity, since light signals are used to synchronise clocks and mark out straight lines in special relativity. Thus, in the presence of gravitational fields, strictly one should only use the general theory. What is done in elementary text books is to add the principle of equivalence on to either Newtonian mechanics or special relativity, whichever is the more convenient. It is an extension in both cases. It serves only as an introduction to the general theory.

A typical approach², considers a light source and detector at the rear and front ends respectively of an accelerating spaceship. The spaceship is considered from

the inertial reference frame in which it is instantaneously at rest, when the light is emitted. Both source and detector have an acceleration a in this frame. The proper length l of the spaceship can be measured using a ruler at this instant. The signal takes a time $t \approx l/c$ to reach the detector, by which time the detector has a speed $v \approx at \approx al/c$ relative to the inertial frame. Provided $v \approx al/c \ll c$, the first order Doppler effect, given by the wave theory of light, is adequate, so that the fractional change in frequency $\Delta v/v \approx v/c \approx al/c^2$.

According to the principle of equivalence, the difference in frequency should be the same, if the spaceship were at rest in a gravitational field of intensity $-a$. Provided $al/c^2 \ll 1$, it is an unnecessary over-elaboration to use the equations of hyperbolic motion, and in a first introductory course the use of Newtonian mechanics and the first order Doppler effect, based on the wave theory of light, is far more convenient. In practical cases $\Delta v/v \sim 2 \times 10^{-15}$ in the experiments of Pound and Rebka and $\sim 2 \times 10^{-6}$ for light from the Sun, so that $al/c^2 \ll 1$, and the simple theory is accurate enough. Near black holes one would have to use the general theory of relativity. This approach, based on the principle of equivalence, should only be treated as a teaching aid, to give a first insight into some of the modifications of both Newtonian mechanics and special relativity required by the general theory of relativity.

Exeter, Devon, UK

¹ Bishop, N. T., and Landsberg, P. T., *Nature*, **252**, 459 (1974).

² Rosser, W. G. V., *Introductory Relativity*, 264 (Butterworth, London, 1967).

³ Pound, R. V., and Rebka, G. A., *Phys. Rev. Lett.*, **4**, 337 (1960).

BISHOP AND LANDSBERG REPLY—We shall explain the points raised by referring to the paragraphs in ref. 1 as $a-e$, those in ref. 2 as $a-c$ and those in ref. 3 as $a-g$. We referred^{3b} to a non-Minkowskian metric. This does not imply that we considered the uniform acceleration to produce space-time curvature^{1a}. We had in mind flat (that is, $R_{\rho\gamma\delta} \equiv 0$) non-Minkowskian metrics of the type⁴

$$ds^2 = g_{44}(x)c^2 dt^2 - \frac{c^4}{4\kappa^2 g_{44}} \left(\frac{dg_{44}}{dx} \right)^2 dx^2 - dy^2 - dz^2$$

We thus agree with Marsh and Nissim-Sabat^{1a} that the existence of a gravitational redshift does not imply space-time curvature, but we do not accept that any

such curvature is suggested by us^{3b}. Rosser^{2a} regards curved light ray paths, and therefore accelerated frames, as unacceptable in special relativity. We^{3d} take the opposite view, which is implicitly supported by Marsh and Nissim-Sabat^{1a}.

For the Newtonian case we used a particle picture of light^{3d} in which light particles are emitted with a constant speed relative to the source, and move according to Newton's laws of particle mechanics. The equality of inertial and gravitational mass leads to the equivalence principle for particles, and thus also for Newtonian optics. From our point of view, therefore, the equivalence principle is completely contained in Newtonian physics, as opposed to special relativity where the principle has to be grafted on, since this theory is not about gravity. Our correspondents disagree with this view (and with each other), the view of Marsh and Nissim-Sabat^{1b} being closer to us than that of Rosser^{2a}. For a wave theory of light (advocated in ref. 2c) the velocity of light is constant with respect to an ether and the equivalence principle does not then apply to Newtonian optics, as also remarked by Marsh and Nissim-Sabat^{1a}. The answer to the question raised there is: "By using a particle picture of light".

An important point of our letter was the view reiterated by Marsh and Nissim-Sabat^{1e} but not taken account of by Rosser^{2b}: the replacement of a uniform gravitational field by a uniform acceleration for source and detector is always magically transformed to a Doppler effect argument for an accelerated detector, thus neglecting the motion of the source. This is a non-trivial step since two times are needed at the source if a frequency is to be defined there. Thus the switch from one model to the other has to be justified, and if presented clearly to beginners^{2c} ought to elicit from them a request for a proof. Our work⁴ may be regarded as providing such a proof for special relativity and, in so far as this had never been done in the past, one was faced by a misuse of the equivalence principle. For Newtonian physics we show⁴ that it is this magical switch in the usual argument that leads apparently to the absurdity of clock retardation by way of the Newtonian Doppler effect. As developed by us⁴, one finds a zero Newtonian gravitational redshift but a non-zero Newtonian Doppler effect for an accelerated detector, and the usual equations for special relativity. These results seem to us clear and consistent.

reviews

IN the study of many subjects, including geography, psychology, statistics, eugenics and meteorology, the name of Francis Galton receives mention from time to time. But few, in their training, receive more than a glimpse of the life and work of this somewhat elusive man. Who was he? Where can one gain a comprehensive picture of him? A visit to the library soon leads to the biography by Karl Pearson, completed in 1930, but this work (2,000 pages) is too much for many readers to face. Thus, for many he is still not within reach. But now the position changes, with the timely publication of this book, and at last we have a manageable and readable account; and one which, although only one-sixth of the length of Pearson's work, is nevertheless much more objective.

The first chapter is concerned with the family background and the life of Galton up to the age of 22 (when his father died). Succeeding chapters describe Galton's years as an explorer, in Egypt, Syria and South West Africa, and contain some fascinating accounts of his experiences. One result of these explorations was the production of the famous book entitled *The Art of Travel*, a book which was of great practical value to those contemplating travel in unexplored territory.

After the years of exploration Galton had much to do with the Royal Geographical Society, and with the development of geography as an academic subject; and he played a large part in having the subject introduced at

Francis Galton: psychology of a polymath

Francis Galton: The Life and Work of a Victorian Genius By D. W. Forrest. Pp. x+340+16 plates. (Elek: London, November 1974.) £5.50.

Oxford University. He also became interested in meteorology, and here he demonstrated his capacity for original scientific research. He studied weather data brought back from Africa by explorers and this led to the discovery of the anticyclone. In 1863 he published a book, *Meteorographica*, containing hundreds of diagrams of climatic conditions in Northern Europe during December, 1861.

By the mid 1860s Galton began to develop an interest in heredity (there is some evidence well documented in this book that the development coincided with a growing realisation that his marriage would probably be infertile). Two chapters carefully trace this interest.

Galton was to a large extent the father of present-day psychology, and several chapters cover in detail his many ideas and experiments in this

field. He was also a pioneer in the development of anthropometry and, at his own expense, set up an anthropometric laboratory as part of the International Health Exhibition held in 1884. His work in this field proceeded with much vigour during the following years and an outstanding development was the technique of personal identification using fingerprints. This work is treated in a chapter devoted to the subject. In 1883, Galton published his last important technical book, *Fingerprints*.

In May 1904 Galton delivered a lecture (at the London School of Economics) to the newly formed Sociological Society, entitled "Eugenics, its Definition, Scope and Aims". This was the birth of the subject of eugenics, and Galton contributed much to the development of this subject. He was by this time, however, into his eighties and his health was on the decline. He died in 1911 at the age of 89.

Professor Forrest's book will be of interest to students drawn from various disciplines. It includes a detailed account of Galton's inventions of various pieces of apparatus, and a bibliography of his published works. It reveals a great deal about the psychology of one who pioneered a good deal of modern psychology (especially with emphasis on the experimental approach), and also a lot about Victorian society in general. The book will be of interest to historians as well as psychologists, biologists and statisticians.

L. S. Goddard

NUCLEAR form-factors measured in elastic electron-scattering experiments decrease with increasing momentum transfer at a rate determined by the nuclear size. If one looks instead at the inelastic region, where the electron loses large amounts of momentum, q , and energy, ν , the cross-section is dominated by quasi-elastic scattering from the individual nucleons in the nucleus, and the q -dependence is a measure of the proton size. In analogous experiments with a hydrogen target, Stanford physicists claimed that in this deep inelastic region they could 'see' the constituents of the proton itself; and the q -dependence indicated that these partons were point particles. Bjorken scaling was observed; apart from kinematic factors the cross-section in this region depended only upon ν/q^2 rather than the independent variables.

Kindergarten parton model

Theory of Lepton-Hadron Processes at High Energies: Partons, Scale Invariance, and Light-Cone Physics. (Oxford Studies in Physics.) By Roy Probir. Pp. x+172. (Clarendon: Oxford; Oxford University Press: London; February 1975.) £6.

Some five years later this "kindergarten parton model" is still very much with us, and Dr Roy's book is a description of these intuitive ideas with their experimental consequences, and the more formal concepts, of scale invariance and

light-cone algebra which have developed from them. The book is likely to be useful to second-year graduate students and 'above'; in the early part it requires knowledge of simple quantum electrodynamic calculations but towards the end the renormalisation group in field theory is called for.

Any introduction to a rapidly changing field can expect to be overtaken by events. Thus, if the author had written the book after the discovery of the ψ particles last November, he would doubtless have stressed the charm quantum number much more. Scaling has influenced the interpretation of deep inelastic proton-proton scattering, but the author has wisely confined himself to lepton scattering where a basic formalism exists and is likely to be of some lasting value.

Heavy nuclei

Heavy Nuclei, Superheavy Nuclei, and Neutron Stars. (Oxford Studies in Nuclear Physics.) By J. M. Irvine. Pp. 158. (Clarendon: Oxford; Oxford University: London, July 1975.) £8.

THE prospective reader who is attracted to this book by the words "superheavy nuclei" or "neutron stars" is likely to be disappointed. Of its 158 pages of text only one chapter of 8 pages is concerned directly with superheavy nuclei, and a further 9-page chapter is devoted to neutron stars. What it does contain is an excellent review of the current theories of the properties and structure of heavy nuclei.

The book concentrates on the region of heavy nuclei beyond ^{208}Pb and as is pointed out in the introductory chapter this contains only ten naturally occurring elements, although a further 14 have been artificially produced in the laboratory. It is perhaps disappointing that the book contains no hint of the excitement and controversy which have surrounded the discovery of these heaviest elements.

The second chapter contains a brief but thorough review of the observed systematics of heavy nuclei such as binding energies, half lives,

decay modes and fission properties. The third chapter then goes on to give a very detailed discussion of the nuclear models, such as the liquid-drop and individual particle models, which have been used to explain these systematic features. Nuclear correlations are introduced here and used to bridge the gap between these two very simple models. The following chapter deals with the particular topic of collective rotations and the specific modifications which need to be considered to bring theoretical predictions into quantitative agreement with experiment.

Nuclear stability and shell effects are next considered and this leads very naturally, through a discussion of fission and alpha decay, to the prediction of the possible existence of superheavy nuclei and the final chapter on neutron stars. A short list of references to relevant review papers and books is included.

The book is written at an introductory level suitable for research students in nuclear structure physics. It is also likely to be of interest to more experienced workers in this field as providing an extensive and thorough review of current theories of the properties of heavy nuclei with a hint and hope of discoveries yet to come.

Come back Aristotle

Confrontation of Cosmological Theories with Observational Data. Edited by M. S. Longair. (International Astronomical Union Symposium No. 63, Cracow, Poland, 1973.) Pp. xi+382. (Reidel: Dordrecht and Boston, Massachusetts, 1974.) Dfl.115; \$38.50.

THIS symposium, held in 1973 to commemorate the 500th anniversary of the birth of Copernicus, provides an excellent picture of cosmology today—of a science caught, as Zeldovich says in his introduction, at a turning point. The programme of Sandage and Tammann to extend the redshift-distance relation for galaxies, the close agreement between the expansion time of the Universe and the age of our Galaxy and other galaxies, and the 2.7 K blackbody spectrum and high degree of isotropy of the microwave background radiation (reviewed here by Blair, Partridge and Boynton) have together convinced all but the most sceptical cosmologists that we live in a hot, big bang Universe.

In paper after paper the most simple, conservative view seems to be supported. Petrosian argues that the cosmological term, introduced and later repudiated by Einstein, is zero. Tammann demonstrates that the velocity flow field of nearby

galaxies is isotropic and linear. Wagoner shows how the cosmic abundances of those elements and isotopes formed primarily in the fireball (deuterium, helium, lithium) favour the simplest type of model, deuterium, in particular, pointing to the existence of the low-density Universe also indicated by the density of matter in galaxies. Steigmann sets severe limits on the amount of antimatter in the Universe.

In his amusing introduction Zeldovich sets out what seems to be a very open minded philosophy of cosmology. That we cannot simply solve backwards in time the equations describing the evolution of the Universe, but have to take arbitrary chosen variants of the initial state and follow the theory of its evolution to the present and thus to a confrontation with observations. The snag of this procedure being that it is dependent on the prejudices, likes and dislikes of authors and "perhaps even their subconscious Freudian attitude to such things as order, chaos, antimatter". Hence the importance of the confrontation with observation, in which "false theory fades".

But is it really cosmological theories that are being confronted with observations? Apart from a few dissenting, sceptical and dissatisfied voices (for example, those of Arp, Kellermann,

Omnes and Elvius), only one theory is discussed in this book. Kuhn's gestalt switch has occurred and the isotropic big bang has become the paradigm. Within that framework the theoreticians set to work on the details: the problem of galaxy formation (Silk, Doroshkevich, Sunyaev, Zeldovich and Ozernoy), the structure of the initial singularity (Penrose, Novikov, Lifschitz and Khalatnikov), and the exciting work on pair creation by anisotropic expansion (Zeldovich and Misner). This is a situation in which the mathematically brilliant but philosophically conservative Russian school of cosmology flourishes. But is it likely that we shall again have to wait the 2,000 years between Aristotle and Copernicus to see this picture overthrown?

Yet even in the ranks of the believers there are some novel perspectives. Hawking analyses homogeneous, anisotropic perturbations of the standard models and concludes that we must be in a unique model (with zero curvature), arguing that the reason for this must be, in a sense, because we are here. If the Universe was not as it is, galaxies and stars could not have formed and we would not be here to observe it—the 'anthropic principle' developed elegantly in a paper by Brandon Carter.

Come back Aristotle, all is forgiven.

M. Rowan-Robinson

Complex uses of an advanced tool

Quantitative Scanning Electron Microscopy. Edited by D. B. Holt, M. D. Muir, P. R. Grant and I. M. Boswarva. Pp. x+570. (Academic: London and New York, January 1975.) £15.50.

SINCE the early 1960s, the accessibility of the scanning electron microscope (SEM) as a working tool in the hands of scientists has grown tremendously. For example, just one of the several SEM manufacturing companies lists over 500 owners throughout the world, which may imply 10 times as many users. Furthermore, a lot of ingenuity has gone into finding new uses for a tool which yields dramatic topographical pictures suitable for hanging on the wall but can also probe the basic electrical and crystallographic properties of materials in many more subtle ways. This book attempts to review the unique methods by which the properties of inorganic materials may be measured quantitatively using the interaction of a rastered kilovolt electron beam with a solid. It explicitly avoids an introductory approach, but, as parts of it evolved from a lecture course, it is well adapted for an advanced teaching course.

Fifteen authors, mainly from British universities, gave authoritative reviews of each use of the SEM and a strong quadripartite editorial team has successfully imposed unity on the contributions, keeping a sharp eye on the possible future development of the instrument. Several aspects of the production of finer and better controlled electron beams occupy the first three chapters, including an unusual and useful review of the very complicated interaction of electrons with solids and a rather casual run through "the approach to 1 Å" by the renowned Albert Crewe. Six chapters on the quantitative interpretation of contrast borrow from and build upon the art developed for the transmission electron microscope (TEM). Howie's chapter does this by means of a unified survey of diffraction contrast and scattering in the TEM mode (including the scanning and glancing-angle modes) and the backscattering mode.

The emissive mode, for all its importance, is compressed efficiently by Gopinath into only 30 pages, but it would not have been too much of a diversion for the editors to have inserted a chapter on the morphology and physics of crystalline organic materials, thereby capturing a large additional readership.

Finally, the versatility of the SEM is suitably revealed in the section on the use of the X-ray yield of the SEM

sample. This section again gives prominence to creative, forward-looking aspects and, indeed, the final chapter on automatic stereological analysis by Jones indicates that a strong use of the imagination and the help of a computer can tell one what is in the bulk of a mineral conglomerate, working only from the surface X-ray energy analysis. The greatest lack I noticed was of any discussion of the positive side of electron beam damage such as is observed with kilovolt electrons on films of alkali halides. In fact, the editors have stuck rather narrowly to the technologically useful metals, semiconductors and phosphors and the emission therefrom.

This book is not a handbook; I regret somewhat the lack of survey tables and appendices. In general, the editors have not pressed their authors to prepare the information better for their readers. Diagrams are redrawn from the research literature rather than pulled apart, condensed and recombined for clarity. The subediting on diagrams is sometimes loose as to symbols and captions, which may cause the neophyte some crises of confidence. These minor points aside, this is a book which the novice microscopist having grasped the basic principles elsewhere, can use with confidence as a guide to the complex uses of the SEM.

Andrew Holmes-Siedle

Maternal lifeline to foetus

The Placenta and its Maternal Supply Line: Effects of Insufficiency on the Fetus. Edited by P. Gruenwald. Pp. x+366. (MTP: Lancaster, April 1975.) £11.50.

THE declining perinatal mortality in developed countries has highlighted the importance of foetal subnutrition *in utero* as an increasingly common cause of perinatal morbidity and mortality. The present volume is therefore well timed and provides a useful summary of current theories concerning the physiology of foetal growth and possible therapeutic approaches to suboptimal growth patterns *in utero*. Professor Gruenwald has a distinguished record in this area, and was one of the first workers to stress the difference between infants of low birth weight due to premature delivery and those due to intra-uterine growth retardation. The volume consists of chapters written by a variety of contributors—usually

research workers with a particular interest in the subject—and there is therefore no uniform style. Many of the chapters are well illustrated, whereas some have no illustrations at all. The illustrations used by the editor tend to be complicated and difficult to interpret at a glance. The majority of authors present an objective view of their subject but in some cases the author's own viewpoint is emphasised with only cursory reference to opposing schools of thought. The book is well referenced and the bibliography is extensive.

On balance the volume presents a comprehensive review of the current literature on placental development and pathophysiology, as well as a shorter section on foetal growth and pathophysiology, not only in human but in other species. The authors emphasise certain areas in which further research is needed, and particularly the need for new diagnostic and therapeutic possibilities in pregnancy. At £11.50 the volume is recommended as a valuable addition to every medical and biological sciences library as well as to interested investigators.

obituary

John Ray Dunning, a pioneer in the development during World War II of the method of isolating uranium 235 used in nuclear weapons and power plants, has died at his home in Florida. He was 73.

Dr Dunning started his graduate career at Columbia in 1929 and was appointed assistant professor in physics in 1935. He toured many European nuclear physics research establishments during the following year and was to become associated with Bohr and Fermi on his return to America. He directed the development of Columbia's first cyclotron, built in 1936, which was to be used in the university's history-making experiments. In determining that uranium 235 is the isotope which readily undergoes fission into

two atoms of nearly equal size and that the reaction releases prodigious amounts of energy, Dr Dunning helped to lay the foundations of the atomic age. He was essentially confirming the results of the enemy in Germany, but his experiments were nevertheless of paramount importance in winning the race to production. He was promoted to full professor in 1946 and in that year served as special representative for the Manhattan District at the first postwar detonation of an atomic bomb on Bikini Atoll. During 1941-46, he was an official investigator of the Office of Scientific Research and Development. From 1942-45 he was director of research in the substitute alloy materials laboratories, which was the official name for the secret gaseous

diffusion project to isolate uranium 235 from 238 for the production of atomic bombs (this process is still the major source of such "fuel"). In 1945 he was appointed director of Columbia's division of war research, and the following year was awarded the Medal of Merit, the highest award made by the US President to civilians. In 1950 he saw the completion of the university's 385 million electron volt synchrocyclotron at Nervis, New York after serving as scientific director of the project.

After 19 years as dean of the faculty of engineering, during which time he had raised over \$50 million for the research effort, he resigned to become Thayer Lindsley Professor in applied science in 1969.

Peace is too politicised for prizes

THE award of the Nobel Peace Prize to Academician Andrei Dimitrievich Sakharov took nearly everyone by surprise. No doubt he could at one time have been considered a candidate for a Physics Prize, but few had thought of him in the context of a Peace Prize. So was the action of the Oslo committee an inspired gesture aimed at expanding the horizons of 'peace' to include human rights as the "only sure foundation for a genuine and long-lasting system of international cooperation"—as the citation read; or was it simply a political act, such as can be carried out from the relative safety of Scandinavia, designed to cause a certain amount of embarrassment to the Soviet Union?

First, let it be said that Sakharov's record, initially as a physicist, then as a proponent of restraint in weaponry and finally as a social democrat fighting for civil rights has been admirable (see page 528). If the year's award is controversial, the controversy is not centred around the personal qualities of Academician Sakharov in any way. Furthermore, it is undeniable that the award of this prize will have done much to encourage Sakharov, if encouragement were needed, to continue his work.

So far so good. But even if the West can, on the whole,

view the award as given for human rights work, the Soviet Union undoubtedly views the award as a piece of political cynicism supportive of troublemakers. If the Nobel Foundation were a political outfit devoted to the supporting of Western ideals that would matter little—but Nobel Prizes would then have the significance only of Stalin Prizes. By aspiring to have a global significance Nobel Prizes must be free of the sort of ambiguity and polarisation that this year's prize generates; and not only this year's—recent awards to Willy Brandt, Le Duc Tho and Henry Kissinger have all in their different ways been political and arguable.

If this means that it is impossible to find globally acceptable recipients of Peace Prizes, then perhaps this is simply a recognition of the fact that the concept of peace is highly politicised and ambiguous, and it is poorly served by the handing out of large sums of money to individuals.

We have noted before that Nobel Prizes often leave a trail of devastation behind them. This is particularly so of the Peace Prize; it is time that the Nobel Foundation seriously looked at other ways of supporting its very worthy ideals.

Better news from the universities

EVEN the most bashful of Britain's universities are now back in business for a new academic year and, according to figures released last week, the population of full-time students (including graduates) is up 10,000 to 261,000. First-year students are up in number by 7%. The reason for the continued growth (albeit at a slower pace than was once predicted) is not entirely that there is a still-growing demand for more higher education among the nation's young. Many of this year's intake will be somewhat reluctant students; the economic situation is persuading many school-leavers that three years at university would be safer than unemployment at 18.

In the past two years universities have been in the forefront of the government's cost-cutting campaign and as a result are now 5% worse off in real terms than they might have expected to be. Sir Arthur Armitage, Chairman of the Committee of Vice-Chancellors and Principals, in announcing these figures, called the meeting of increased demand and the maintenance of university education under these circumstances "no mean contribution to public policy". Few will disagree with him, and

many will hope that the so-called fat-trimming exercise is now at an end.

Behind the overall figures are two statistics; one encouraging, one less so. Even though there are still 10,000 empty science places, there is good evidence that the swing away from the natural sciences has been halted. On the other hand the postgraduate scene is still very static and there might even in the near future be such a thing as a shortage of people with postgraduate degrees. The proportion of overseas students in the postgraduate population remains high.

With 300 university teaching posts now frozen for lack of funds, it is incumbent on universities to enunciate a policy for when (if ever) there is a thaw. There has been a strong element of chance in the freeze—departments with staff at retirement age have been particularly vulnerable. But it is not necessarily logical simply to put the same posts back on the market. A crisis of this dimension offers an excellent opportunity for change in a system normally gripped by tenure. It would be foolish to throw up such an opportunity.

THE 30th Report from the Select Committee of the House of Lords on the European Communities is a slender pamphlet which at first glance seems too trivial to merit a column in *Nature*. It comments on two draft directives from the EEC: one about pollution on bathing beaches (an unseasonable topic anyway, at this time of year), and the other about pollution from wood pulp mills, of which there are only seven in Britain.

In fact the report is anything but trivial. It raises a matter of high principle in Britain's relations with the EEC, affecting our whole policy for the control of pollution. On October 13, the House of Lords "took note" of the report and there was a short debate on it. The debate ought to go on outside Parliament as well.

The matter of principle is this. The Council of the European Communities agreed, in a declaration on November 22, 1973, that "improvement in the quality of life and the protection of the natural environment are among the fundamental tasks of the Community". Admirable. No-one would dissent from this. It follows that there must be a policy among the member states for the abatement of pollution. This policy is now being worked out through numerous draft directives from Brussels prescribing standards for car emissions, lead in petrol and crockery, sulphur in oils and, most recently, the pollution per tonne of product from pulp mills and the quality of water in which bathing is "authorised or tolerated".

The philosophy underlying these directives is to fulfil the 1973 Declaration by imposing identical and uniform standards upon all member states, from Italy jutting into the Mediterranean to Scotland jutting into the Atlantic, irrespective of the diversities in the environments of these states. There is a Gallic elegance and simplicity about this, but it is quite inconsistent with the pragmatic policies which determine the procedures for pollution control in Britain. Do we stick to our present practice and persuade the EEC to accept it? Or do we submit to these inflexible directives from the Community?

Before arguing this point we have to distinguish three kinds of standard, for this controversy with the EEC is concerned with only one of these three kinds. There is a good case for uniformity over product and design standards (for example, the level of pesticide residues in foodstuffs and the emission standards from car exhausts) because food and cars move from one part of the Community to another. There is also a case, provided it is not made too rigid, for long term objectives for the purity of the air and of

the sea. The controversial question is whether there should be Europe-wide identical standards for the quality of emissions into the air from smoke stacks and of effluents into rivers and the sea from outfalls. In other words, must specifications for the discharge of wastes into the environment be identical irrespective of the capacity of the environment to disperse or dilute the wastes?

The practice in Britain is empirical. The consents to discharge effluents, issued by a Regional Water Authority, depend on the capacity of the river or estuary, the uses to which it is being put, the pollution load it is already carrying and so on. The licence to discharge "noxious vapours" into the

A community of interests?

ERIC ASHBY

air, issued by the Alkali Inspectorate, depends on the best practicable means for controlling the vapours at the time the works was erected, the cost of installing new equipment, the economic state of the industry and so on. In brief, the British "philosophy" (if one can call it that) is not to minimise pollution, nor to bring all discharges of any pollutant down to some uniform level (though there are guidelines for quality standards for emissions): it is to optimise pollution levels so that the capacity of the environment to accept (and in many cases to recycle) pollutants is fully used, but not abused, and industry (and thus employment) are not unduly put at risk. (Rabid conservationists need to be reminded, sometimes, that all pollution except that from atomic weapons is a by-product of processes which benefit society.) This "philosophy" can be defended on two counts: it makes the best use of the limited resources available for the control of pollution; and it acts (as the Alkali Inspector put it in a report published in 1888) as "an

elastic band ever tightening as chemical science advanced". Thus in the sulphuric acid industry in Britain there are plants emitting 5%, 4%, 2% and now 0.5% of the sulphur burnt. These different levels are related to the best practicable means for control at the time the plants were built. Had we been obliged to adopt a uniform emission standard it would either have been too lax for new works or it would have added unreasonably to the costs of running older works.

Consider now the EEC's draft directive for effluents from wood pulp mills. It lays down that within 10 years pollution shall be reduced to levels set out in the directive. These prescribe the biological oxygen demand (BOD) and suspended solids (SS) per tonne of product, above which discharges from mills will not be permitted. There is an escape clause which allows derogations from these standards if the discharge is into tidal waters, provided the discharges "do not cause an appreciable deterioration in the quality of the receiving water" ("appreciable" is not defined!). But the derogations expire after a maximum of 10 years. So this is what the directive means: that ultimately the permitted effluent standard from a wood pulp mill shall be identical, whether the mill discharges into the Thames or the Rhine or into the Atlantic Ocean off the Scottish or the French coast.

It requires no subtlety to see that this sort of rigidity would be a wasteful way to deploy the limited resources we have for the abatement of pollution. But the EEC has another reason for pressing uniformity on member states. It asserts that if the Scottish mill discharging into the Atlantic can get away with less stringent effluent standards, this will constitute unfair competition against the mill on the Rhine, which has to comply with very stringent standards. This is a phoney argument, for you might as well say that the wage rates and the transport costs for the Scottish mill will constitute unfair competition unless they, too, are identical with the rates and costs for the mill on the Rhine. "Harmonisation" of practices (as the EEC calls it) among member states is obviously a sensible objective, but it becomes irrational if it disregards the great diversity of environments in the Community.

The draft directive for the quality of bathing water is unacceptable for a different reason. It is not that we are content to bathe in dirtier water than our common market cousins bathe in; it is that a code of control which might be appropriate on a Mediterranean beach at a temperature of 27 °C would be inappropriate on an Aberdeenshire beach at a temperature

(under favourable conditions) of 10 °C. The EEC directive goes into great detail about the monitoring of beaches where bathing is to be authorised or tolerated. (How does one deal with a bather who persists in bathing in a place which is not tolerated? The directive is silent on this point.) Monitoring must be carried out for each beach once a week, or once every two weeks, or once a month, depending on "the mean density of bathers per kilometre of beach" and bathing is defined as "prolonged immersion of the whole body". Bathing water is "deemed to conform to the mandatory values of the relevant parameters if 95% of the samples . . . comply with the limits specified in column I of annexes 1 and 2". Now turn to the list of parameters in the annex. They include: total coliform, faecal coliform, faecal streptococci, *Salmonella*, viruses, pH, mineral oils, surface active substances reacting with methylene blue, phenol indices, pesticides, and the following: As, Cd, Cr, Pb, Hg, CN, NO₃, phosphates and dissolved oxygen. Consider the task of carrying out these acts of monitoring, even for the major watering places round the coasts of Britain. The Department of the Environment hazarded a guess that the cost of complying with the directive might be of the order of £100 million a year. If there were a demonstrable health hazard this enterprise might be justified, but such data as we have (from a Medical Research Council report published in 1959) indicate that although many beaches in Britain are offensive to the eye and the nose, they are not a hazard to health; and the WHO still takes the view that "there are no internationally accepted criteria for the quality of coastal water for bathing with respect either to microbial contamination or chemical pollution".

There are no grounds for complacency about the state of the environment in Britain. We are certainly not in disagreement with the EEC's Declaration to protect the environment and we have, in the Control of Pollution Act, the best legislative arrangements in Europe for doing the job. The matter of principle, on which I hope Britain will stand firmly, is that each member state should be free to fulfil the objectives of the Community's environment policy in the light (as the Declaration states) "of health and ecological requirements"—that is to say, taking into account the uses to which the environment is being put, and its capacity to dilute or disperse wastes. This is the basis of our pragmatic style of pollution control. This is the style we shall have to abandon if we cannot persuade the EEC to make its directives more flexible. □

Candle power at Browns Ferry

In his third article on the state of the US nuclear industry, Colin Norman recalls the bizarre and dangerous accident at a nuclear power station earlier this year.

A FIRE, started by an electrician with a candle, disabled the Browns Ferry nuclear power station in Alabama on March 22, 1975, and sent shock waves through the nuclear industry. Officially described as the most serious accident to occur so far at an operating nuclear power plant in the United States, the fire knocked out several key safety systems, caused problems in shutting down one of the plant's two reactors, and rekindled the long-smouldering debate about nuclear safety.

A bizarre and dangerous accident which destroyed some 2,000 electric cables and caused millions of dollars worth of damage, the fire has put the Browns Ferry power station out of action for an indefinite period. It has also raised a number of serious questions about the vulnerability of nuclear power plants to such unforeseen incidents, and it may result in some costly modifications to other nuclear power stations in the United States.

The nuclear industry has, however, managed to salvage some good news from the incident. Although several key safety systems were disabled by the fire, enough reserve systems were left intact to shut the plant down safely and to avoid a major accident. That, industry spokesmen suggest, supports their contention that there are so many safety features built into a nuclear power station that if one device fails, others will be left to take over if necessary.

The Nuclear Regulatory Commission (NRC), the agency responsible for regulating the nuclear industry and ensuring that nuclear power plants are safe, shares that interpretation. In testimony before the Joint Committee on Atomic Energy last month, for example, the Chairman of the NRC, William A. Anders, said "we believe that this unfortunate and serious occurrence has shown that the reliance on the defence-in-depth concept is sound for the protection of public health and safety".

The NRC is now in the midst of analysing the Browns Ferry fire and its implications. It has already published a factual report on the accident, and in the next few weeks, the NRC will

recommend changes in design and operating procedures at other nuclear power stations to prevent similar incidents from occurring elsewhere. Its report on the fire itself is a disquieting document which reveals an astonishing lack of fire precautions, considerable confusion during the fire fighting operations, and some quick thinking in the control room to avert a major nuclear disaster.

The fire began at about 1215 on March 22, when two reactors at Browns Ferry were each generating about 1,100 MW of electricity. A third reactor, of similar size, was under construction. The fire was touched off by two electricians who were testing for air leaks around cables passing through the wall of a room enclosing the Unit 1 reactor.

The air in the reactor room is maintained at a lower pressure than the air outside, so that if radioactivity were released from the reactor, it would not immediately be dispersed into the atmosphere—fresh air would tend to leak into the reactor room rather than contaminated air out of it. The electricians were checking for leaks in a part of the wall separating the reactor room from a cable spreading room, immediately beneath the reactor's control panels. They were using the highly unofficial but time-honoured method of holding a lighted candle to the outside of the wall at the point where cables pass through it—if the candle flame is sucked horizontally, air is leaking from the cable spreading room into the reactor room.

An electrician's mate, who was doing the candle work, told NRC investigators that a fire started when the candle flame was sucked into a hole in the wall and ignited polyurethane foam surrounding some cables. He tried to beat out the smouldering foam with a flashlight, but succeeded only in burning the flashlight lens. He then tried to smother the fire with rags, but that didn't work. Somebody brought him a carbon dioxide fire extinguisher, but the CO₂ blew straight through the hole without extinguishing the fire. Fanned by the air rushing through the hole, the fire began to get further back into the wall. He tried firing off two dry chemical fire extinguishers, but without success, and about 15 minutes after the fire started, the evacuation alarm sounded in the cable spreading room where he was working.

The cable spreading room evacuated in preparation for tripping the permanent carbon dioxide extinguishing system. In the time, another electrician rang the alarm in a roundabout way (the fire alarm telephone number listed in some plant manuals, so there was sor

and the reactor operators in the control room were notified of the fire. By that time, the burning had travelled through the hole in the wall into the reactor room, where several cable coatings had caught fire. Firefighting efforts there were hampered by the fact that the burning cables were about 40 feet above floor level. The local fire department was notified at 1309 and fire trucks arrived at 1330 from Athens, about 10 miles from the plant.

Among the alarming features of the firefighting effort noted by NRC investigators were the following:

- The carbon dioxide system initially failed to work because the power had been shut off and metal plates had been placed over the manual cranks to guard against accidents during construction work.
- Smoke in the reactor building was so dense that the room was evacuated at about 1300, and "there appears to have been no central organised direction of the fire fighting efforts in this area until approximately 4.30 p.m."
- Soon after he arrived at the plant, the Athens fire chief recommended spraying the fire with water, but the plant supervisor refused to allow use of water because of the danger of electrical shorts and injury to the fire fighters. He eventually sanctioned the use of water at about 1900 and the fire was extinguished within 15 minutes. It was formally declared to be out by 1945. By that time, the fire had damaged cables about 40 feet into the reactor room and a few feet inside the cable spreading room.

In contrast to the firefighting efforts, attempts to shut down the reactors were more successful, but no less dramatic. Because some key equipment had been disabled by the fire, the reactor operators were forced to use what the NRC coyly describes as "unconventional" methods to shut one of the reactors down and to avoid a potentially serious situation.

The reactors are controlled in a common control room immediately above the cable spreading room. The operator in charge of the Unit 1 reactor started noticing strange behaviour of various indicators on his control panel about five minutes after he had been notified of the fire. He was getting erroneous indications that pumps were running, some pumps cut in automatically, power output from the reactor began to drop, and several lights on the control board began glowing abnormally bright and then getting dim or going out. At 1251, the operator decided to shut the reactor down by inserting the control rods into the core, thereby cutting off the chain reaction (in operator's parlance, he manually 'scrammed' the reactor).

That successfully halted the nuclear

reaction, but the problems then began. Because radioactivity decay of fission products in reactor fuel continues to heat the core long after the chain reaction is shut off, cooling water must be circulated through the core for many hours afterwards. Unless adequate cooling is provided, the reactor core could melt, burn its way through the concrete and steel floor of the pressure vessel and release large quantities of radioactivity into the environment. Because means of supplying cooling water to the reactor were knocked out by fire, the operator in charge of Unit 1 had to improvise.

Among the most important systems which were disabled was the emergency core cooling system (ECCS), a device which is supposed to flood the core with water if a pipe ruptures and the main cooling water is lost. The ECCS is used routinely during reactor shut-down operations.

According to the NRC report, and a description of the event provided to the Joint Committee on Atomic Energy last month by Donald F. Knuth, Director of the NRC's Office of Inspection and enforcement, the following sequence of events took place after the reactor was manually scrambled.

The water level surrounding the core dropped as a result of reduced boiling when the chain reaction was shut off. Consequently, pumps designed to inject water at high pressure into the reactor vessel increased their flow rate to keep the core covered with water. Soon after those pumps began running, however, a steam valve closed and disabled them. At that stage, the NRC report states, there was the following dangerous situation:

"The reactor coolant system had one remaining source of high pressure water, the control rod drive (CRD) system. Operator M (who was in control of Unit 1 operations) increased the CRD pump output to its maximum. Although the control room instrument has a maximum scale reading of 100 gallons per minute, Operator M stated that he knew that the CRD pump was pumping greater than 100 g.p.m. but he does not know how much was being pumped. Operator M advised the investigators that he did not think that starting the spare CRD pump would have resulted in significantly greater injection flow, and he recalls that the spare CRD pump was not always operable during the shut-down".

In other words, there was only one reliable means of injecting high pressure water to the reactor, and that was being strained to its limit to maintain the coolant level around the core.

It soon became apparent that the SRD pump system couldn't maintain

water level. It was therefore decided to open relief valves to reduce pressure in the reactor so that low pressure pumps could be used to supply cooling water. That tricky operation was carried out at about 1330, and the low pressure pumps provided sufficient water until about 1830, when control over the relief valves was lost and they slammed shut. Pressure in the reactor began to build up, and the low pressure pumps were rendered inoperable.

The operator was then forced to switch back to the CRD system to supply high pressure water. That arrangement provided sufficient coolant until about 2150, when control over the pressure relief valves was restored and the reactor was again depressurised. About 13 hours after the fire began, temporary repairs were completed to allow the reactor to remain at low pressure, and at about 0430, normal means of cooling the core were restored. By a series of extraordinary procedures, which have won praise from the NRC investigators, the reactor operators were therefore able to shut the plant down safely. But the incident nevertheless raises some very tricky questions.

Aside from the astonishing comedy of errors which led to the fire and caused it to burn for nearly 7 hours when it could have been extinguished with water in a few minutes, inadequacy in the design of the Browns Ferry plant was highlighted by the accident: a single fire, in a relatively small area of the plant disabled several key safety systems. Could a similar fire at another plant also have such potentially disastrous consequences?

Investigators from the NRC are now looking into the implications of the fire for other plants. According to Dr S. H. Hanauer, who is directing the investigation, important cables in plants built since Browns Ferry are more widely separated so that fewer key systems would be disabled by one fire. But "further improvements may be prudent in the light of the Browns Ferry lessons", Hanauer suggested, and he added that "some rerouting of cables may be necessary in some existing plants". Nevertheless, Hanauer stated that "based on our evaluation of the incident, we believe that even if a fire such as the one at Browns Ferry occurred in another existing plant, the most probable outcome would still be with no adverse effects on the public health and safety". The investigation, Hanauer said, "has not shown that present power plants are unsafe".

But the Browns Ferry fire had the makings of a very serious nuclear accident, and it has already provided plenty of ammunition for nuclear critics to shoot at the nuclear industry's otherwise good safety record. □

THE deficit in this year's grain harvest can hardly have come at a more embarrassing time for the Soviet planners. Just when internal propaganda is aimed at high output and increased productivity, at greeting the forthcoming Twenty-fifth Party Congress in a spirit of "socialist emulation" and celebrating the fortieth anniversary of "Stakhanovite" work, the Soviet government has had to admit, at least at the international level, that in spite of an ever-expanding programme of the mechanisation and electrification of agriculture, the harvest has once again failed to meet the basic requirement of feeding the Soviet population.

Scanning the Soviet press, it is difficult at first glance to find evidence of the deficit. On October 3, when the Soviet government was already seeking abroad the grain which it had failed to produce at home, *Radyans'ka Ukrayina* reprinted a speech of V. V. Shcherbyts'kyy, First Secretary of the Communist Party of Ukraine, which claimed: "Twenty regions have already fulfilled the agricultural plan [for grain delivery] ... and nine regions have overfulfilled the firm plan." Similar news has peppered the Soviet press throughout August and September. Collective farms, state farms, districts and regions have been reported, one after another, as fulfilling the plan.

Yet when one reads more carefully, a somewhat different picture emerges. Immediately before announcing his apparently promising picture of overfulfilled plans, Shcherbyts'kyy had admitted that hopes for a good harvest had fallen victim to "extremely unfavourable weather conditions", but that nevertheless, the total yield would be "considerably higher than in 1972" (cold comfort, since 1972 was the year when crop failures resulted in considerable food shortages). Later in the same speech, he mentioned the importance of guaranteeing adequate supplies of animal feed—implying that this year's reserves were dangerously low, if not actually insufficient. It may well prove necessary to slaughter off a considerable number of cattle on the collective cattle-rearing farms.

It should also be remembered that even if grain production quotas have been fulfilled, in the sense that the requisite amount has been delivered to the official collecting points, a bad harvest may mean that a collective farm is left with no surplus to be shared out for the support of its members and their domestic livestock for the coming year, causing the farm members to become, temporarily, consumers rather than producers, and necessitating a further depletion of

the country's livestock. Shcherbyts'kyy's speech refers, of course, only to Ukraine, but reports from the other grain areas of the Soviet Union, notably Kazakhstan and western Siberia, paint a similar picture.

The emphasis on delivery to the state of the prescribed quotas is fundamental to Soviet agricultural policy. In the early days of collectivisation, this led to considerable wastages. Forbidden by Draconian legislation to reap any grain for their personal use before the plans were fulfilled, peasants had to let their horses and oxen starve for lack of feed-

Alien corn?

from Vera Rich

stuffs, and so had no beasts left to draw the reapers when harvest could officially commence. Although such a situation would hardly be likely today, the precarious balance of Soviet agriculture, officially based on collective or state farms, but in reality deriving a considerable proportion of its vegetables and other small scale products from the personal allotments which the farmers cultivate in their free time is still liable to break down under any unusual conditions. Press announcements that peasants have been stealing "collective" grain to feed to their "private" cow or chickens can hardly account for deficits of millions of tonnes, but do, in some way, symbolise the whole problem of Soviet agriculture. The collective/state farm system simply cannot meet the demands made on it. At the popular level, the solution is that proposed by the Twenty-Fourth Party Congress: more mechanisation, more extensive use of fertilisers. The theoretical journals, however, show a deeper concern.

Last year, writing in *Planovoe khozyaistvo* (No. 3, 1974) the Chairman of the State Planning Commission noted a recent falling off of theoretical and methodological work on balancing the economy. Several follow-up articles in the same journal show considerable concern with the balance of the agricultural and industrial sectors. Similarly, writing in *Voprosy ekonomiki* (No. 8, 1975), M. Bronshtein, Corresponding Member of the Academy of Sciences of the Estonian SSR made an extensive analysis of the "Economic and Social Problems of the Industrialisation of Agriculture". The word "industrialisation" is significant here—Soviet planners see agriculture as being essentially one more branch of industrial production, amenable to the same system of fulfilment and overfulfilment of plans. The present trend towards

specialisation and concentration of different branches of the "industry" in different areas often, however, takes too little account of the fact that agriculture is what Bronshtein calls a "biomechanical system". His article is tentative and theoretical, but it does reflect a certain awareness that agriculture has its special problems which will not necessarily respond to an industrial-type treatment.

Although such discussions do take place at the theoretical level, however, Party policy demands the acceptance of the fundamental superiority of the Soviet agricultural system. On October 7, the Deputy Minister of Agriculture, A. A. Gol'tsov made a statement in passionate defence of the system. Although the final figures are not yet in, he said, an "average" harvest is expected. The Soviet Union is one of the world's leading grain producers. Grain yields are well up to international standards. Export and import of grain is "normal practice" in international trade. Grain purchases from the USA are intended for the Soviet Far East, to obviate the long haul across the Trans-Siberian railway. The Soviet Union not only imports grain but also supplies it to other countries. Protesting far too much, he then drew attention to the "steep growth" in agricultural production which has taken place since the 2.3 million tractors and 600,000 combines of today replaced the 17 million wooden harrows of Tsarist times. He stressed the great social benefits that collective farm life has brought to the peasants. Unfortunately, his argument breaks down on one vital fact—Tsarist Russia was a major grain exporter, the "breadbasket of Europe."

Four days later, addressing a rally of collective farmers, the Minister of Agriculture, Dmitrii Polyanskii, spoke far more realistically, admitting that "unusual weather conditions" would inevitably be reflected in the general level of agriculture as a whole. It is one thing, however, to admit a sudden emergency, but another to suggest that the system itself might be at fault. For this reason, although in the present atmosphere of detente the Soviet government is entering into all manner of trade agreements with Western and Third World countries, even in such sensitive areas as oil production or nuclear fuels, there has so far been considerable reluctance to make a firm agreement on grain purchases. Present negotiations, although described as being in a "very delicate" state, seem, however, to be moving towards the concept of a regular sale agreement. The stabilisation of the grain market thus produced of long term benefit to both

international news

Sakharov and the cause of peace

from Vera Rich, London

THE announcement last week of the award of the 1975 Nobel Peace Prize to Academician Andrei Sakharov coincided neatly with the 250th anniversary celebrations of the Soviet Academy of Sciences. This event, however, was not claimed by the academy as a culminating point of the celebrations, a tribute, as it were, to the efforts of Soviet science in the cause of peace. For the very activities which have won Sakharov the Peace Prize have brought him into disfavour with the Soviet establishment, and although he still retains his status as an academician, he does so on sufferance.

Sakharov's involvement in problems of peace and human rights has arisen as a direct corollary of his scientific career. After defending his PhD thesis (on cosmic-ray theory) in 1947, and after publishing only three scientific papers he disappeared from the world scientific scene into a top-secret establishment working on the development of the H bomb. At this stage in his career, Sakharov was convinced that a balance of power was the only sure guarantee of world peace and, "carried away by the immensity of the task", he contributed several key ideas to the research, although he has always eschewed the title of "father of the Russian H bomb" conferred on him by Western journalists, stating that the project was essentially one of "collective invention".

At the same time, together with Igor Tamm, he began working upon non-military aspects of thermonuclear reactions and plasma physics. It was for his work on the bomb, however, that he received (secretly) a Stalin Prize, three Orders of Socialist Labour, and a salary of 2,000 roubles a month, with numerous fringe benefits, such as access to restricted consumer goods, a chauffeur-driven car and a round-the-clock bodyguard. His election, in 1953, as a full member of the Academy of Sciences, without passing through the intermediate stage of corresponding member, was likewise a result of the military aspect of his work.

During the 1950s, however, Sakha-

Sakharov and his wife, Yelena Bonner: academician on sufferance.

rov's attitude to the nuclear arsenal began to change. He became increasingly concerned with the genetic and pollution effects of nuclear fallout, and also with the tremendous consumption of resources and manpower involved in making bombs. From 1958 onwards, he campaigned consistently against nuclear tests—earning from Khrushchev the comment that Sakharov was a good scientist, but should leave politics to the politicians. This, however, Sakharov was not prepared to do, and the campaigns continued. Finally he was able to urge the acceptance of a test-ban treaty covering the atmosphere, space and the ocean.

In 1964, Sakharov became involved in the great debate of the Academy of Sciences and the Academy of Agricultural Sciences which, after a quarter of a century of Lysenkoism, led to the reinstatement of genetics as a respectable branch of Soviet science. This event, apparently only an internal matter of academic policy, was to have great psychological significance for Sakharov. By now he was experiencing a complete revulsion from the whole concept of nuclear weaponry. He was increasingly disturbed by the ethical problems engendered by the bomb and by the often cynical attitude of politicians towards such problems. At this point, as a result of his participation in the Lysenko debate, he became acquainted with the biologist Zhores Medvedev, and through him with his

twin brother, the historian Roy. The Medvedev brothers introduced Sakharov to *samizdat*, the growing body of clandestine, self-published typewritten literature, which circulated among the growing circle of those who would later be called dissidents. In 1968, Sakharov made his own contribution to *samizdat* literature with a monograph entitled *Progress, Coexistence and Intellectual Freedom*.

This manuscript circulated widely in *samizdat* and inevitably reached the West, where it received considerable publicity. The Soviet government accordingly revoked Sakharov's security clearance, and it was almost a year before he could find another post—as a "senior researcher" at the Lebedev Physics Institute, the lowest grade of post in which an academician can legally be employed. Two years later, Sakharov published a second "manifesto", which was also signed by Roy Medvedev and a physicist, Valentin Turchin. This took the form of an open letter to the Soviet leaders, claiming that the major internal problems of the Soviet Union, the slowing down of the economy and a failure to meet the challenge of the "second industrial revolution" of the computer age could only be met by increased democratisation.

From now on, Sakharov was to be increasingly concerned with the problems of the individual. In November 1970, he formed, with Andrei Tver-

dokhlebov and Valerii Chalidze, a Human Rights Committee, maintaining that in doing so he was acting within the guarantees of the 1936 Soviet Constitution. Since then he has campaigned unceasingly for the release of dissidents illegally confined in mental institutions, for the rights of Jews to emigrate to Israel, for the abolition of the death penalty, for the rights of minority communities within the Soviet Union, for the amnesty of political detainees. In doing so, he has brought down on himself considerable pressure from the authorities and open attacks in the Soviet press which, in 1973, evoked fears that a show trial might be imminent.

His large personal fortune, amassed during his work on the H bomb, he donated, some years ago, to the Soviet government's Cancer Research fund, and although retaining his status as an academician, the material benefits normally accruing to such a position have steadily vanished. Furthermore, his scientific career has been interrupted by the "inner unrest" and by the increasing demands of all those who have come to regard him as a kind of ombudsman for the dissidents. He admits that he has "not been productive" of recent years, and on occasion has suggested that his most fertile years are behind him. Those who have had occasion to speak with him on scientific topics (mostly young refuseniks and others who find it difficult to continue their scientific career under the prevailing conditions) maintain, however, that his insight and scientific intuition is as active as ever and that a conversation with Sakharov can throw a whole new light on their work.

The award of the Nobel Peace Prize to Sakharov may be seen by many to contain a certain paradox. His early involvement in the H-bomb programme and his growing involvement with internal abuses in the Soviet Union rather than with the broad issues of peace between nations—these may seem strange qualifications for a Peace Prize winner. But it was in his involvement with thermonuclear weapons that Sakharov first came face to face with the ethical problems involved in their use; seeing peace and detente as the only alternative to a nuclear holocaust, and believing that the desire for peace is shared by the majority of mankind, he believes that the only sure guarantee of peace is that of a democratically based society, in which governments will permit a free discussion of all issues which concern the community and which, in the words of the Nobel citation "the inviolable rights of man . . . serve as the only sure foundation for a genuine and long-lasting system of international cooperation."

THE business of exporting nuclear technology to countries which are not signatories to the Nuclear Non-proliferation Treaty (NPT) has come in for serious criticism after the 'leaking' of secret documents implicating West Germany in the development of a South African programme capable of supplying nuclear weaponry. In Bonn, members of Chancellor Schmidt's government have spent the past few days issuing denials of involvement, denials of denials and even (from State Secretary Klaus Boelling) a 'correction' of his denial to make it an affirmation that Kraftwerksunion (KWU) had indeed asked for an official guarantee to export nuclear reactors to South Africa.

The row has already led to the resignation of Lieutenant General Gunther Rall, the West German representative on NATO's military committee, who was said to have visited South Africa secretly and under a false name, as a guest and adviser of the South African Defence Department. It has also led to a general reassessment of a policy under which Bonn has agreed, in spite of US opposition, to supply to Brazil a package deal involving a complete nuclear fuel cycle which would allow, if required, the manufacture of weapons-grade material.

The debate has been escalated by the news that Egypt has asked Bonn to cooperate on its nuclear programme, and that South Africa is reported to be planning the sale of 14,000 tons of uranium oxide to Iran in a deal which would give Iran a part share in a large uranium enrichment plant, capable of producing fissionable material and based in South Africa.

One of the most awkward problems in controlling the spread of nuclear weapons is the establishment of a mechanism to ensure that equipment and material supplied for civilian use is not actually converted to a military end. The West German-Brazilian deal brought the problem sharply to the attention of the countries capable of managing such sales (the USA, the USSR, France, West Germany, Japan and Britain) and they are reported to be having confidential talks to draw up a set of rules to govern nuclear exports. Whatever the outcome of the talks (and it is said that a set of safeguards is likely to be agreed by the end of the year) it looks as though the German-South African deal will go ahead, in spite of a rather vague undertaking from Bonn that the political implications as well as the economic will be considered before it agrees to issue a licence to KWU to build reactors for South Africa.

But even if the sale does go ahead, its accomplishment will be attended by a good deal of embarrassment for both the West German and South African governments. And the laying bare of the coy, undercover exchanges by which the two countries corresponded has been a thoroughly successful public relations exercise on the part of the African National Congress (ANC), which was responsible for the exposé.

Documentation for the deal, including the secret telegram which led to the downfall of Lieutenant General Rall, was among matériel believed to have been stolen by a spy from the South African Embassy in Cologne. It was published by the ANC in an account entitled "The nuclear conspiracy: FRG [Federal Republic of Germany] collaborates to strengthen apartheid".

According to the ANC, a uranium enrichment plant to be built in South Africa next year has been developed with the assistance of the state-owned Gesellschaft für Kernforschung (GFK) and the state-controlled company STEAG, with the agreement and active participation of the Bonn government. The prototype plant, it is estimated, will cost \$1,400 million to install, and an ancillary power station costing a further \$800 million will have to be constructed in order to provide energy for the process.

After making comparisons with the costs of conventional fuel sources, the ANC argues that a uranium enrichment plant in South Africa cannot be justified economically on energy grounds, and can only be explained in political and military terms. As Pretoria has refused to sign the NPT, the ANC claims, it will be able to use the enrichment plant "to produce uncontrolled material for nuclear weapons. The threat of proliferation could be used to deter embargoes and sanctions, while the threat to use nuclear weapons could be used to extend apartheid's hegemony on the continent of Africa. The use of nuclear weapons cannot be precluded as a desperate measure to preserve the apartheid state."

The suggestion is not simply paranoia on the part of a struggling black nationalist group. The South African state-owned broadcasting corporation reported only last week that "more and more countries are acquiring nuclear power stations, and with them the automatic capability of making nuclear weapons", and many of the country's leaders are committed to the development of a nuclear arms capacity as an integral part of a civil nuclear programme. □

THE European Science Foundation (ESF) last week marked its first year of existence with the publication of its first annual report and with a simultaneous venture into the field of public relations. Although it has clearly decided that it is now ready to present itself to the scientific community, the foundation did not have much in the way of positive achievement to report, other than its readiness to tackle the tasks it has set itself. Sir Brian Flowers, the foundation's first president, was, however, able, in part at least, to fend off a good deal of scepticism about the organisation's future effectiveness.

Sir Brian made clear last week that the sole aim of the foundation is to further international cooperation in new scientific schemes. He admitted, however, that little had been done during the past year apart from "organising the organisation", though one or two definite moves have already been made towards coordinating research projects. These include the incorporation into the foundation of the pre-existing European Medical Research Council (EMRC) and Western European Science Research Council (ESRC) and the setting up of an *ad hoc* Committee for Space Science and a Standing Committee on Astronomy. More specifically, the foundation has managed to implement international research projects in fields as widely scattered as genetic manipulation, particle physics, and the preservation of mediaeval stained glass.

But Sir Brian denied that the foundation will ever be called upon to fulfil any role other than overseeing cooperation in pure research and preventing unnecessary duplication, adding that he saw no need for the ESF to become involved with the "interface between politics and science". From that relatively shaky standpoint it was easy for him to defend the ESF against sceptics expecting an easy time at the expense of an organisation operating on a budget of £200,000 with a full time staff of six based in Strasbourg. Nonetheless, the foundation still has to weather its first storm, and though its board may insist that the ESF can be effective in ensuring that there is no repetition of the situation whereby Britain, France and Germany all expend individual effort on the construction of broadly similar particle accelerators, it remains to be seen what weight the foundation carries when it comes to national chauvinism. At the moment there is optimism that the foundation will be able to influence participant governments through its member organisations—Britain's include the five research councils, the British Academy and the Royal Society—though what would happen, in the absence of finan-

cial control by the foundation, should these organisations themselves revert to nationalistic stances has not apparently been considered by the board.

All the same, Sir Brian's resolution and view of himself as first and foremost a European must count for something, and he instils an undeniable air of confidence throughout the foundation. He insists that the ESF should be run with a human touch, perhaps acceding to the point often made that it was established to pre-empt the bureaucracy of the Brussels administra-

Strasbourg diary

by Allan Piper

tion. Though not in as many words, what he apparently advocates is a return to grass roots policy-making, but within a pan-European framework. In a rare display of emotion last week, he expressed horror at the notion that the foundation should become nothing more than a central computerised clearing house of research data, preferring instead to envisage the setting up of "a little piece of Europe" for the scientific community.

Whether or not that small international community can expect to grow much larger in the near future is on the surface as indeterminate as many other aspects of the foundation. Though the admission to the foundation last Wednesday of the Greek National Hellenic Research Foundation brought the number of member organisations to 43, representing 16 countries, Sir Brian did not evince much enthusiasm for the suggestion that countries from the eastern bloc be admitted. Yugoslavia has, in fact, been a member since the founding of the ESF but Sir Brian feels that, though approaches from other communist countries would not be discouraged, the foundation for its part would be better off spending the next five years or so consolidating its position and will not make any overtures in that direction.

For the more immediate future, the Executive Council of the ESF has just passed fresh proposals recommending research projects involving, among other things, the general place of biology in space research, patterns of

human migration within Europe, the difference between existing European legal systems, and methods of teaching advanced mathematics. That selection identifies the eclectic scope covered by foundation, and illustrates the point made by everybody connected with its running that the word "science" should be interpreted in a broad European sense of knowledge or learning. Whether or not such an essentially academic approach will be able to survive in the latter half of the twentieth century only time will tell; in the interim, it is as well to share the optimism of the ESF representative who feels that when heads need knocking together, as they surely will, Sir Brian Flowers is the right person to do it.

● Out on the eastern edge of the city, in a solid concrete building unflatteringly reflective of a more substantial international role, the Parliamentary Assembly of the Council of Europe (CE) was last week convened for a nine-day plenary session. Ample evidence there of the political-scientific interface mentioned by Sir Brian Flowers. Essentially a political organisation the council has set up a European Joint Committee of Scientific Cooperation (EJCSC) comprising a mixture of scientists and parliamentarians engaged in the running of research groups and working parties. One obvious advantage which the council has over the ESF lies in the political muscle it has developed over 26 years of existence; thus, any findings coming out of the EJCSC may eventually come up for consideration by the council's Committee of Ministers, so that pressing issues of practical concern stand some chance of being satisfactorily resolved at an international level. During last week's session, for instance, the issue of pollution of the Rhineland water table came up for discussion. The problem is that the water table, lying below the surface, provides 80% of the water reserves for an area that covers parts of France, Switzerland and Germany, so that both the consumption and the pollution of the water transcend national boundaries. In the past there has been little attempt at international control but by bringing the issue to the attention of the CE a coordinated approach should be ensured over the coming months. It may seem invidious to compare the workings of a small, newly formed organisation expressly unconcerned with the problems of technology, with a well established political body working on a multimillion pound budget, but the comparison does illustrate that, whatever else the ESF may aver, politics and science are becoming ever more inseparable.

● There was an unmistakable air of satisfaction during the session over the

THE Natural Resources Defense Council (NRDC), which has long been a prominent thorn in the flesh of the nuclear industry, has now launched a drive for stricter radiation standards in the United States. In petitions filed during the past two weeks with the Nuclear Regulatory Commission (NRC) and the Environmental Protection Agency, NRDC staff scientists Arthur Tamplin and Thomas Cochran argue that workers exposed to radiation at the present maximum permissible levels run an unacceptable risk of dying from cancer and of having children with serious genetic defects. Consequently, they argue that the permitted exposure levels, at least for younger workers, should be reduced by about a factor of 10.

On the basis of several reports and studies published in the past few years (particularly a 1969 report by the International Commission on Radiological Protection and a report on the biological effects of ionising radiation (BEIR) published in 1972 by the National Academy of Sciences), Tamplin and Cochran have calculated that between 2 and 6% of all radiation workers exposed to whole-body radiation at maximum permissible levels for their working lives could die from radiation-induced cancer.

Though they point out that few radiation workers are in fact exposed to the maximum permissible levels of radiation, Cochran and Tamplin suggest that such a risk is "excessive" and that the standard is an "inappropriate guideline" for the nuclear industry.

Similarly, the petition contains calculations suggesting that workers in the nuclear industry who are exposed to maximum permitted levels of whole-body radiation would stand between a 1 in 10 and 1 in 300 chance of having children with serious radiation-induced genetic defects.

The present maximum allowable whole-body dose of radiation is 5 rem a year, and no more than 3 rem in one calendar quarter. Cochran and Tamplin argue that the standard should be replaced by a requirement that workers under the age of 45 should receive no more than 0.5 rem a year to the whole body, and not more than 0.3 a quarter.

Older workers would be allowed higher radiation doses—up to a maximum of 3 rem a quarter, however.

A two-tier exposure level, Cochran and Tamplin argue, would offer the greatest protection to those most susceptible to radiation injury, such as pregnant or fertile women, while not at the same time applying the strictest standards to other parts of the workforce. "Hence, the proposed changes

Washington seen

by Colin Norman

should not place a large burden on the industry", they argue.

If the NRDC's proposals were adopted, the greatest impact would be felt in fuel-reprocessing and plutonium-fabricating plants, but no such facilities are yet in commercial operation. The immediate effect of the petition, however, is likely to be to reopen the long standing debate about the consequences of long term exposure to low levels of ionising radiation.

● Following recent revelations that the Central Intelligence Agency (CIA) and the Department of Defense have been carrying out ethically bankrupt research on people—such as feeding psychotropic drugs to soldiers without their knowledge or consent—Senator Edward Kennedy has proposed a bill to establish a Presidential commission to oversee all federally supported clinical studies.

The bill would essentially transform a panel which was established by Congress last year to draft regulations governing human experimentation supported by the Department of Health, Education and Welfare, into a permanent body with broad responsibilities. Called the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, the panel has already issued recommendations for research on foetuses, and it is now trying to draft guidelines for research on prisoners, children and the mentally ill. It is expected to complete its work early next year.

Kennedy said last week that the abuses perpetrated by the CIA and the Department of Defense "underscore

the need to expand the national commission's jurisdiction, and to expand it now". His bill would add the Secretary of Defense, the Secretary of Health, Education and Welfare, the Director of the CIA, four Senators and four Representatives to the panel's 11 existing members. It would also establish the commission as a permanent advisory body with responsibility to make public recommendations on clinical studies sponsored by all government departments.

Since Kennedy is the chairman of the Senate Health subcommittee, to which the bill was referred, and since it is also backed by two senior republicans on the subcommittee—Jacob Javits and Richard Schweiker—it stands a very good chance of being passed by the Senate.

● The latest in a long line of statements by prominent scientists warning about the dangers of nuclear power was made public with considerable fanfare last week. It is particularly noteworthy for two reasons. First, it resulted from a study sponsored by the National Council of Churches—a body with considerable influence. And, second, it was supported by a galaxy of scientific stars, including 14 Nobel Prizewinners.

Called "The Plutonium Economy: A Statement of Concern", it warned about the dangers of allowing plutonium to be extracted from spent reactor fuel rods and recycled as a nuclear fuel, and it spoke out against the development of the fast breeder reactor. "We believe that the proposed 'plutonium economy' is morally indefensible and technically objectionable", the statement said.

Drafted by a committee chaired by Rene Dubos and Margaret Mead, and supported by a lengthy background report on the dangers of plutonium, the statement was requested by the National Council of Churches last year. After remarking on the dangers of using plutonium, the report concludes that "all who believe that technology should serve human values should join in opposing the plutonium economy and in seeking to divert into more constructive channels the vast resources being devoted to nuclear power."

council's role in the setting up of the recently formed European Space Agency (ESA). As long ago as 1960 the council was calling for one European agency to handle the building of both launchers and satellites, and the amalgamation of ELDO and ESRO last May was regarded by most delegates as the results of persistent lobbying by the council. The feeling of achievement was celebrated last week by the assembly when it unanimously

agreed a draft recommendation that member states of ESA meet at least once a year at ministerial level. The feeling is that ministerial meetings will provide the agency with an impetus which might otherwise be lacking.

American confidence in the agency has been demonstrated by a request for the ESA to cooperate in NASA's post-Apollo programme: a space laboratory is to be built by European industry under the guidance of the agency.

Apart from scientific and technological benefits, a fully independent ESA could also provide industry and employment—there is even a whisper that the agency ought to become outwardly commercial and seek to establish new markets within the Third World. One delegate, perhaps mindful of the approach of 1984, even expressed relief that with a fully independent space industry Europe will be in the running for worldwide communications control.

First-year ecology

SIR,—Although I sympathise with many of the sentiments expressed by Dowdeswell and Potter (October 2) it seems to be that some of their difficulties could be overcome by giving up the search for "natural" habitats (which hardly exist in Britain) and instead concentrating on the immediate surroundings. Take, for example, the ordinary suburban garden. Its high diversity of plants supports an immense variety of animals (most of them insects) and an array of ecological situations reminiscent of tropical rain forest. Virtually all the principles necessary for a first-year ecology course can be demonstrated and investigated in a garden. There is no shortage of material and an imaginative ecologist is soon able to find examples of what he wants.

There are populations of aphids, ladybirds, earthworms, and woodlice for practical work in population ecology. There are intricate food webs centred around every plant and tree. The onion bulb fly, the two-spot ladybird, the peppered moth, and a host of others, can be used as examples of the gene as an element of continuity in populations. I think that the trouble is that rather little is known and published about the ecology of gardens. Research money, as we all know, has gone to the study of "natural" areas and farmland and gardens have been dismissed by some ecologists as biological deserts, which is a pity, for here is a vast expanding resource invaluable to teacher and conservationist alike. Indeed the fact that so little is known should be exploited in the development of a spirit of inquiry among first-year students. Finally, although I would not dispute the value of simulation experiments and visual aids I remain sufficiently old-fashioned to believe that direct contact with nature is better.

Oxford, UK

Deterioration

SIR,—Whereas the quality of the scientific contributions to *Nature* remains uniformly of the highest calibre, I have noticed over a period of several years a steady deterioration in the quality of editorial contributions.

A recent example (August 21) is the

astonishing revelation that the old Chinese had discovered relativity, galaxies, perhaps pulsars and X-ray stars. Surely the author should re-read his classics to find out that, far from being 1,300 years behind, western thought was in fact several hundred years ahead of these Chinese speculations.

In Lucretius's *De Natura Rerum* (about 55 BC), for example, we find also ideas about empty space ("All nature as it is in itself consists of two things—bodies and the vacant space in which they are situated", Book I, 418) and about time and space ("It must not be claimed that anyone can sense time by itself apart from the movement of things", Book I, 460). All this was preached by Democritus in the fifth century BC, but many other examples of anticipations could be found in the writings of Greek philosophers.

I fear that the review article in question is indicative of a spirit of masochistic depreciation of science in general and Western culture in particular, which is regrettable in the offices of so prestigious a scientific journal. Many readers will also remember that ample space was given to an Indian journalist for a vicious attack against the USA and the WHO, and that only several months later did the editor feel obliged to shed some crocodile tears in an editorial more designed to whitewash himself than to put things right.

Yours faithfully,

Dr S. V. VAECK

Hofstade, Belgium

Collectors' Code

SIR,—In recent years there has been a good deal of comment on the remarkable zeal shown by some American bird and egg collectors, which led to much discussion at the XVI International Ornithological Congress in Canberra last year (*Nature*, 248, 543; 249, 793; *New Scientist*, 64, 734; 1974). The leading American learned society, the American Ornithologists' Union, set up an *ad hoc* committee under the eminent conservationist John Aldrich to consider the whole matter, and they have now produced a lengthy report.

After emphasising the number of birds killed by hunters and pest-control agencies and the need for scientists to have adequate freedom to

obtain specimens, with which few reasonable people would argue, it ends by advocating some relaxation of local controls, on which it is difficult to comment without more knowledge of the local situation, and proposing a "Code of ethics for collectors and capturers of birds" with which few can disagree and doubtless most will warmly welcome. Since you were at one time very helpful with this campaign, and since the code surely deserves careful study by members of many disciplines throughout the world it may be useful to reprint it:

- The privileges of a collecting or capturing permit shall be used only to obtain specimens for justifiable scientific or educational purposes.

- Collect or capture specimens only from those populations or species that can sustain the loss of individuals.

- Collect or capture only those specimens that are deemed necessary and that can be properly cared for or prepared

- Exercise the greatest care in recording accurately the maximum amount of relevant data for all specimens obtained.

- If live birds are collected, maintain them under humane conditions with high standards of health and sanitation.

- Collect with the aim of making available all relevant data obtained from specimens, either through publication or by giving access to the data.

- Abide by all stated regulations, including the use of authorised permits to collect, capture, import, export and trans-ship specimens.

- Notify the appropriate local authorities of plans to collect or capture birds in areas under their jurisdiction.

- Identify yourself and your purposes to those who may witness your collecting or capturing in order to inform them of the validity of your activities.

- Be as judicious and humane as possible in collecting and capturing activities, taking care to respect the rights, interests, and feelings of others.

- Regard the privilege to collect or capture birds as a trust in the pursuit of science; it should never be flaunted.

Yours faithfully,

W R. P. BOURNE

news and views

THE application of nuclear magnetic resonance (NMR) spectroscopy to biochemical systems is increasing at a prodigious rate, with the emphasis now clearly in the direction of enzyme-substrate interactions. As more and more sophisticated interpretations are brought to bear on indirect measurements, it becomes increasingly difficult for the people most interested in the biological implications of the experiments to follow the reasonings and assess the significance of the results. What, for example, does the fact that ion A is $x(\pm y)$ nm from atom B of substrate C bound to enzyme D tell us, in the absence of crystallographic data on the crystal structure? Those who have such reservations will surely welcome the trend exemplified by a research group from the National Institute of Medical Research in London. This group has been pursuing investigations into the enzyme dihydrofolate reductase, and its latest paper (page 564) concerns the direct observation by ^{31}P NMR spectroscopy of NADPH (a dinucleotide cofactor in the enzyme reaction) bound to this enzyme. The authors have been able to study some properties of the bound molecule directly, revealing some facts about the nature of the binding, and are clearly very close to being able to determine its conformation, well in advance of the determination of the enzyme structure by more conventional means.

Biological studies using ^{31}P NMR have been relatively few compared with those using proton NMR. This has been due largely to two factors. First, nearly all biological molecules contain hydrogen, but not all contain phosphorus.

NMR and enzyme binding

from G. E. Chapman

Second, the sensitivity of ^{31}P to NMR detection is about an order of magnitude less than that of protons, and hence correspondingly higher concentrations are needed. But ^{31}P has some distinct advantages over protons for NMR study. In particular the chemical shift range is greater, and linewidths are less than those of protons on the same molecules. This means that more fine structure may be observed in the ^{31}P NMR spectrum of a large molecule than in its proton NMR spectrum, and hence there is more potentially useful information to be extracted.

The earliest published papers in this branch of biological NMR dealt with nucleotides and related molecules, where the technique was used principally to investigate solution conformations in conjunction with proton NMR. Then work began to appear on phosphoproteins, nucleic acids and phospholipids, but it is probably fair to say that the triumph of observation outweighed any other scientific significance, at least in the earlier publications. A paper on ^{31}P NMR of tRNA fractions by Gueron (*FEBS Lett.*, **19**, 264; 1971) appeared to show the promise that conformational information could be derived from the chemical shift perturbations of the phosphodiester groups (in the same way that has been done for proteins by proton

NMR) but little has been heard since in this direction. The application of Fourier transform techniques to NMR caused a dramatic decrease in the concentrations of nuclei needed for observation. As a result of this, Richards and his coworkers at Oxford could achieve the remarkable feat of monitoring the changing levels of phosphorus-containing tissue metabolites in an intact muscle during tissue death, using ^{31}P NMR (*Nature*, **252**, 285; 1974). This highlights the potential value of NMR as a non-destructive assay technique. This type of experiment has been extended to the study of a developing embryo. There appears to be an additional bonus in that the chemical shift of the inorganic phosphate resonance makes possible an estimation of the intracellular pH without physiologically perturbing the system.

Evidence is accumulating that ^{31}P relaxation is dominated by chemical shift anisotropy at high magnetic fields. This apparently esoteric tidbit is not without significance to prospective researchers in the field: in essence it means that the resolution of chemically different phosphorus nuclei in a sample, far from being increased by going to higher magnetic fields will probably be decreased. Thus there is much scope for work at the field strengths attained by conventional magnets, rather than using the much higher field (and costlier) superconducting magnets.

It is to be expected that ^{31}P NMR will play an increasing role in the study of biological systems at the molecular level. □

BRIGHT meteors often leave a faint, persistent luminosity along the visual path after they have passed. For most meteors this luminous train lasts for a very short time, but for some it may be observable for seconds, minutes or even an hour. This persistent train is not formed along the whole path of the glowing meteor nucleus but only along that part of the path which falls within a specific height region of the atmosphere, usually between 85 and 90 km above the Earth. The colour of the train is green or yellow, fading to white as the train decays, the observed spectrum consisting of very few bright lines. Trains illuminated by sunlight, however, are red or orange, mainly due to the reflection of sunlight from the

Persistent meteor trains

from David W. Hughes

fine dust particles left behind the ablating meteoroid. Trains expand laterally at a rate of about 1.6 m s^{-1} , so a train which persists for an hour is about 11 km across at the end of this time. Train luminosity, I , decays according to the formula $I = (a + bt)^{-2}$ where a and b are constants and t is the time.

Many meteor trains appear double after a time, the train gradually becoming a tube of luminous matter which,

viewed from the side, appears like a double line of light. This effect may be caused by the dying out of the luminosity along the train axis or by the expanding edge of the train having a greater luminosity. If the luminosity was distributed evenly throughout the cylindrical train it would appear brightest in the centre when viewed from the side. During their lifetime the trains are blown about by the prevailing winds in the mesopause region of the atmosphere and in the first quarter of the twentieth century meteor train movement was the only indicator of the winds and turbulence in the upper atmosphere.

Meteor showers differ strikingly in the relative numbers of persistent

meteor trains produced. For example, about 50% of the meteors in the Perseid shower (which maximise around August 13 each year) leave trains, while only about 5% of the Geminids do so (maximum rate on December 14) Plavec (*Bull. astr. Insts Csl.*, 2, 19; 1949) concluded that the relative number of trains depended on the geocentric velocity of the meteoroids in the shower, this being 60 km s⁻¹ for the Perseids as opposed to 35 km s⁻¹ for the Geminids. Lindblad (*Meddn Lunds astr. Obs.*, Ser. 1. No 189; 1956) found that there was a direct linear relationship between the mean visual magnitude of the train and its duration, the brightest lasting longest. Also brighter meteors were more prone to have trains. Meteor magnitude, however, is not the only factor to be taken into account and often during shower observations bright meteors appearing in the same part of the sky and within a few seconds of each other differed radically in train-forming ability. Lindblad carried out radar and visual studies of the same meteor and found a clear tendency for radar echoes of exceptional duration to be associated with the presence of a visual train. In fact the train formation process is statistically more closely linked to the phenomena of a long duration echo than to that of a bright meteor—it is more dependent on the ionisation produced by the meteoroid than on the luminosity. In the magnitude range +2 to -1 the radar echo duration is twice as long for the train-forming meteor as for the non-train meteor.

The mechanism responsible for the persistent luminosity is still something of a mystery. In 1907 Trowbridge (*Astrophys. J.*, 26, 95) suggested that gas phosphorescence was the cause and compared the phenomena with the afterglow produced in a gas by the electrodeless ring discharge. Chapman (*The Aurora and Airglow*, edit. by Armstrong, E.B., and Dalgarno, A., 204, Pergamon, 1955) thought it unlikely that the source of energy emitted over so long a period could be the meteor itself, and suggested that the luminous energy was drawn from a pre-existing store in the atmosphere itself, such as the energy of dissociation of oxygen. It is also necessary to explain why some but not all meteors from the same stream and of the same brightness produce trains. Chapman suggested that meteoroids contain some catalyst that can draw on the atmospheric store of energy and convert it into light and that this catalyst is only present in sufficient quantities in a certain percentage of the meteoroids. Sodium, which as the normal airglow shows can glow through the night, was suggested as the most probable candidate: it would

transform atomic oxygen to molecular oxygen by converting the dissociation energy of O₂ into sodium light.

Baggaley in this issue of *Nature* (page 567) produces quantitative calculations of the energetics of this sodium process. The complete sequence of necessary chemical reactions is known together with their relative rate coefficients. Also the concentration of sodium in the incident meteoroid is known with fair confidence because meteoroids have been found by spectroscopic analysis of the emitted light to have the same elemental composition as carbonaceous chondrite meteorites. The persistent trains seem to be confined to the 85–90 km height region of the atmosphere and rocket borne mass spectrometers have yielded the chemical concentrations of O, O₂, O₃ and N₂ in this region.

Using all these observations Baggaley concludes that a meteor of magnitude about -10 (that is a tenth as bright as the full Moon) is required to introduce enough sodium to account for the observed luminosity. These very bright meteors are exceedingly rare—13 times rarer than the persistent meteor trains which last more than half an hour.

So it seems that the sodium process cannot provide sufficient luminosity and aeronomists must think again. Possibly the role of ionised species and the peculiar tube-like appearance of the train provide a clue. □

Information transfer in mammalian cells

from M. Bobrow and E. Solomon

Part of this article was inadvertently omitted last week. The earlier part described several situations in which genetic information, varying in amount from the whole nucleus to a small chromosomal fragment, can be transferred between different types of eukaryotic (and particularly mammalian) cells.

Transfer of genetic information by isolated mammalian DNA was claimed some time ago by Bendich, Borenfreund and Honda (*Informative Molecules in Biological Systems* (edit. by Ledoux), 81, North-Holland, 1971). Chinese hamster cells were incubated with mouse DNA and 1 in 10⁵–10⁶ cells subsequently appeared to react with an antiserum made to mouse cells. The alterations in these cells has not been further characterised. In a somewhat different situation, the technical difficulties in work of this sort are well demonstrated by the recent evidence (Kleinhofs *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, 72, 2748; 1975) that bacterial

contamination was responsible for early claims of the integration of isolated DNA into plant chromosomes. There is always the possibility that misleading results can be given by bacterial, mycoplasma, or viral contamination of the material used.

The same group (Bendich, Borenfreund, and Sternberg, *Science*, 183, 857; 1974) have recently investigated another potential system for transfer of genetic information. Mouse spermatozoa were coincubated with Chinese hamster fibroblasts and a proportion of these fibroblasts acquired the capacity to react with an antiserum to mouse embryos. Similar results have been obtained with rat sperm and Chinese hamster fibroblasts and were reported in *Nature* last week (Higgins *et al.*, *Nature*, 257, 488; 1975). Clones of cells from these experiments react with an antiserum to rat embryo, but have no detectable rat chromosomes on karyotyping. This situation is therefore somewhat similar to the various experiments described earlier, in that a genetic function appears to be transferred in the absence of any specifically identifiable chromosome from the donor. The HPRT enzyme transferred by way of isolated metaphase chromosomes has, however, been well characterised by a variety of independent techniques as being of donor species origin, whereas the information transferred by coincidence with spermatozoa has thus far been defined only by immunofluorescence with a relatively crude antiserum to an undefined antigen in murine embryonal tissues.

Spermatozoa are a cell type evolved specifically to the function of cell fusion and the transfer of genetic information; and yet (although it is difficult to document from the published literature) many workers have tried without success to use spermatozoa in cell fusion experiments of various sorts. The specific interest in transferring genetic information from sperm as opposed to any other cell source is that if the technique could be sufficiently refined it would open the way to direct analysis of meiotic products, give access to a genome which has not yet been modified by the processes of tissue differentiation, and it could conceivably throw some light on the natural process of fertilisation. The possible production of embryonal antigens, and their relationship to malignant change is the particular interest of the group presently investigating this system.

The experimental transfer of eukaryotic genetic information by nuclear transplantation or virus-mediated cell fusion has already been proven of tremendous value in several fields of biological research. Whether a similarly bright future awaits the recently de-

scribed techniques for transferring smaller amounts of genetic information is difficult to predict. If, with the development of appropriate selective systems, it should turn out to be regularly possible to introduce bits of chromosome containing one or a few specific genes into host cells, this could turn out to be of major significance.

Year of the ψ

from W. T. Toner

The Lepton-Photon Symposium was held at Stanford University on August 21–27.

It is appropriate that this year's Lepton-Photon Symposium was at Stanford where many of the discoveries which have revitalised high energy physics have been made. Pride of place went to new results from electron-positron annihilation, many of them obtained at the host laboratory.

The spectroscopy of the ψ , as it stood before the symposium, was reviewed in *News and Views* for September 11. Two new states were added at the meeting, to make a total of at least eight. R. Schwitters (SLAC, Stanford) reported data from the SLAC-Berkeley collaboration showing a fourth ψ -like particle of mass 4,400 MeV and width 50 MeV, produced directly in electron-positron annihilation. B. Wiik (DESY, Hamburg) and J. Heintze (Heidelberg) both presented evidence for the decay chain $\psi(3095) \rightarrow \gamma X(2800) \rightarrow \gamma\gamma\gamma$, and Wiik tentatively suggested (on the basis of two events) that X may also decay to proton-antiproton pairs. Spins and parities remain to be determined except for the two lightest ψ s (1^-), but the uncanny resemblance of the level structure to that of positronium (Mills *et al.*, *Phys. Rev. Lett.*, **34**, 1541; 1975) left few to argue against some form of charmonium interpretation (Appelquist *et al.*, *Phys. Rev. Lett.*, **34**, 365; 1975; Eichten *et al.*, *ibid.*, 369).

If 1975 is the year of the ψ , 1976 may well be the year of the lepton. Earlier this year M. Perl (SLAC) had reported on 24 anomalous events of the type $e^+ + e^- \rightarrow \mu^\pm + e^\mp +$ unobserved particles, of which only 5 could be background from conventional processes. G. Feldman (SLAC) discussed the extension of this analysis to cover the whole of the SLAC-Berkeley data, leading to a total of 86 events, of which no more than 22–30 could be from conventional processes. It is possible that these events are due to the production and weak decay of a pair of charmed mesons, but the most

popular explanation (as yet without proof) is that the reaction is $e^+ + e^- \rightarrow U^+ + U^-$ where U is a heavy lepton, a member of the series e, μ, \dots and decays to $\mu \bar{\nu}_\mu \nu_U \rightarrow \nu_U$ is the neutrino associated with U. The excitation curve suggests a mass of about 1.9 GeV for U.

The most apt comment in the 36 years of our attempts to understand the leptons, is Rabi's "Whoever ordered that?", of the muon. With a third member of the series one might begin to make progress. F. Gilman (SLAC) remarked that the U (if a lepton) has been found where charmed mesons were expected, just as the muon was found where Yukawa's pion was sought. He left unspoken the outrageous thought which occurred to more than one member of the audience: that there might be a connection between the masses of these leptons and hadrons—the pion is not much heavier than the muon, and the charmed mesons (when found) should have masses ~ 2 GeV. H. Harari (Weizmann Institute) presented an imaginative scheme linking leptons to hadrons in another way: the electron to the u and d quarks which are found in ordinary matter, the muon to the s and c quarks to be found in strange and charmed particles respectively, and the U to new t and b quarks, which would make up other families of particles yet to be discovered.

L. Lederman (Columbia University) discussed old and new data on the direct production of the old leptons (muons and electrons) in the strong interactions of protons, a process that should not take place to any appreciable extent, but does (*News and Views*, March 13). The plot seems to be thickening, with reports of enhanced production, relative to pions, at small transverse momentum, which rules out any explanation in terms of large transverse momentum phenomena, and also makes it difficult to explain the effect in terms of any very heavy particle decaying into lepton pairs. There is experimental confusion at low energies, with new data from a Pennsylvania-Stony Brook collaboration showing direct lepton production at energies as low as 10 GeV, in agreement with Leipuner *et al.* (*Phys. Rev. Lett.*, **34**, 103; 1975), but in disagreement with Winter (*Phys. Lett.*, **B57**, 479; 1975) and with Russian data reported to the symposium. The new discoveries at the electron-positron storage rings do not seem to be related to the high-energy direct lepton production in any obvious way, and if direct leptons are indeed produced at low energy, a relation between the two is extremely unlikely. There is no explanation for this phenomenon, nor even any estimate of its likely significance. As his conclusion,

Lederman showed a blank transparency.

The symposium would still have been stimulating without all this excitement. There was, for example, the strong evidence presented by Schwitters for the production of back-to-back jets of particles in electron-positron annihilation at 7.8 GeV, in beautiful agreement with the parton model; there was the report by W. Lee (Columbia University) of the first clear observation of the long sought decay of the ρ' (1600) into two pions; and a great deal more. There was also the 'monopole' event (Price *et al.*, *Phys. Rev. Lett.*, **35**, 487; 1975), which L. Alvarez (Berkeley) argued, most convincingly, was probably caused by the fragmentation of a platinum nucleus in the detector.

There was such euphoria about the new physics that several theorists—Gilman, Harari, C. H. Llewellyn-Smith (Oxford) and J. D. Bjorken (SLAC)—went out of their way to remind us that much of the interpretation rests on plausible assumptions, which remain to be proved. This will require a searching re-examination of the old physics as well as the new. \square

More headaches from star formation

from M. G. Edmunds

A RENEWED discussion of the interpretation of observational studies of the radio spectra of molecules in the Orion nebula will probably make star formation theorists reach for their aspirin bottles. The theory of star formation is complex and difficult; the refinements of competing physical processes that can be invoked are almost infinite, and yet even the most simplified models gobble up large amounts of computing time, only to leave the proponents arguing about numerical errors.

The basic model attempts to follow the self-gravitational collapse of a cloud of interstellar medium into a state where it is hot and dense enough for the start of nuclear energy generation and the birth of a star. Any observational constraints on the theories are invaluable since the conditions involved must range over many orders of magnitude in temperature and density as the formation proceeds. The presence of large amounts of finely-divided dust in the dense gas clouds which are the site of star formation means that radiation at optical wavelengths is obscured and the probing of the physical conditions can only be achieved with radio and infrared techniques. One of the happiest hunting grounds for the elusive observational data has been the region of the Orion nebula, which includes both the optically visible region of gas heated

by young hot stars, and a nearby extended region of high infrared luminosity believed to represent a nursery of stars in the process of formation.

Zuckerman and Palmer (*Astrophys. J. Lett.*, **199**, L35; 1975) consider the molecular lines in the radio spectra of the Orion infrared complex. They point out that the lines show a composite spectrum of a sharp spike superimposed on a broad plateau. The widths of the lines may be attributed to broadening by the Doppler effect as a result of gas motions; the spike implying velocities of about 4 km s^{-1} and the plateau implying much larger velocities of perhaps 30 km s^{-1} . While the low velocity region extends over a large region, the high velocity region appears much smaller and is centred on an area where the infrared emission is very high, including the sources known as the Becklin-Neugebauer object and the Kleinmann-Low infrared nebula. It therefore seems that the gas in a small region of Orion experiences much greater motions than the rest of the nebula. The most obvious interpretation is an increased velocity as a result of a conservation of energy and angular momentum during the collapse of part of the gas to form a protostar. But it is puzzling that inorganic molecules such as SiO, SO, H₂S are far more prominent in the high velocity region (compared with molecules containing carbon) than in the low velocity region. Since the

conditions required to excite the lines of these inorganic molecules are very similar to those required for the organic compounds, the implication is that the molecular composition of the gas in the Orion nebula is not homogeneous. Zuckerman and Palmer speculate that the elemental composition of the gas may not be homogeneous, and if this were the case then the consequences for the chemical composition of the forming stars would be fundamental. A less extreme view is that the conditions for molecule formation differ between the kinematically distinct regions, while the elemental abundances remain constant.

There is an alternative interpretation of the observations. Zuckerman and Palmer recall the suggestion that the Becklin-Neugebauer object represents an evolved F star whose radiation is very reddened by dust (Penston, Allen and Hyland, *Astrophys. J. Lett.*, **170**, L33; 1971). Indeed, the only other "plateau" molecular line source yet found is a carbon star whose molecular spectrum shows organic molecules formed from outflowing gas rich in carbon synthesised by nuclear reactions during the star's evolution. The Orion plateau source could therefore be explained as a region of gas ejected from a normal evolved oxygen-rich star in which molecules formed from oxygen dominate over those formed from carbon. There have been objections to the interpretation of the very strong

Becklin-Neugebauer object as a reddened evolved source, but if the above argument is correct there is justification for the view that at least some of the infrared sources in the Orion complex represent evolved stars rather than natal protostars.

The more depressing news is that Zuckerman and Palmer snatch away from theorists some observational determinations of the magnetic field in regions of star formation. They suggest that the existence of high velocity broadening effectively vitiates a recent determination of a very strong magnetic field by the Zeeman-effect broadening of SiO lines. They also point out that observational selection effects in OH line Zeeman-effect determinations, and uncertainties over what density of region these maser lines originate in, exclude such measurements as a guide to the general magnetic field within the nebula. They finally suggest that the measurement of polarisation of infrared emission induced by the alignment of grains in a magnetic field will not even give the field to an accuracy better than a few orders of magnitude. All this is very frustrating to model makers since, in a slightly ionised gas cloud, the magnetic field acts as an effective pressure and may be considerably enhanced as the cloud collapses. The strength of the field is thus an important parameter in determining the dynamics of the collapse. □

HALF the elements of the first transition series, namely manganese, iron, cobalt, copper and zinc have biochemical roles which are well documented and, in the main, thoroughly investigated. Of the remaining five elements of the series the investigation of three is increasing in popularity. Since 1911 (Henze, M., *Z. physiol. Chem.*, **72**, 494) vanadium has been known to occur in high concentration in the blood cells of ascidians—sea squirts—although neither its function nor its chemistry is yet understood. More recently both chromium and nickel have come under scrutiny for possible biological roles.

Chromium is now known to have an important function in nutrition in both man and animals, being involved in glucose metabolism (Merz, W., *Physiol. Rev.*, **49**, 163; 1969). Dietary studies have shown that induced chromium deficiency in rats and monkeys leads to impaired glucose tolerance, giving rise to a diabetes-like syndrome. This observation naturally led to studies of the effect of chromium on the action of insulin. Enhancement of the response of adipose tissue and mitochondria to insulin was observed with many chromium (III) species although

Biochemistry of transition metals

from A. J. Thomson

non-labile complexes such as [Cr(III)(ethylenediamine)]³⁺ were ineffective. In view of the recent detailed structural studies of insulin by Hodgkin and co-workers (*Proc. R. Soc.*, **B186**, 192; 1972) this problem invites further examination.

Nickel stood out among its transition metal neighbours as apparently being without biological effect. Sunderman and his colleagues have long sought one, concentrating at the outset on the toxicity of nickel carbonyl (*Ann. N.Y. Acad. Sci.*, **199**, 300; 1972). They have now demonstrated that nickel is maintained in the blood sera of man and experimental animals at levels between 2 and $12 \mu\text{g l}^{-1}$. The element is especially abundant in rabbit serum, facilitating isolation of a protein containing nickel, termed nickeloplasmin, which immunoelectrophoresis identified as an α_2 -macroglobulin. The protein has a high molecular weight ($>7 \times 10^5$) and contains 0.9 g atoms of

nickel per mol of protein. Now a group of Australian workers (Dixon, N. E., Gazzola, C., Blakeley, R. L., and Zerner, B., *J. Am. chem. Soc.*, **97**, 413; 1975) have advanced the claim that jack bean urease is a metallo-enzyme containing nickel. Although it was the first enzyme to be crystallised by Sumner in 1920 the metal content had escaped detection. This group has now succeeded because they had available a large quantity of highly purified enzyme. Atomic absorption and gravimetric analysis gives an estimate of 2.0 ± 0.3 g atoms of nickel per 105,000 g of enzyme. The electronic spectrum has been recorded and confirms the presence of the d-d transitions of the nickel (II) ion. Since the extinction coefficients of octahedral nickel (II) d-d transitions are very small, usually of the order of $10 \text{ mol}^{-1} \text{ cm}^2$, the detection of these bands requires long path lengths of highly concentrated material. For example, to detect the spectrum of nickel (II) in carboxypeptidase A, in which the naturally occurring zinc ion had been replaced by nickel, it was necessary to use 50-mm path length cells and $\sim 5 \times 10^{-4} \text{ M}$ protein to yield absorbance values of only ~ 0.05 (Rosenberg, R. C., Root, C. A., and

Gray, H. B., *J. Am. chem. Soc.*, **91**, 21; 1975). It is presumably partly for this reason that the nickel ion in urease has remained hidden for so long.

Vanadium is present in high concentrations in the blood cells of certain tunicates, marine animals which feed by filtering seawater. The metal is contained within clusters of vacuoles, called the vanadophores, each about 2 μm in diameter, which are themselves housed in the blood cells or vanadocytes, 8 μm in diameter. The vanadophores, which are pale green, are known to contain vanadium (III) ions and 1.8 N sulphuric acid. But the exact nature of the vanadium ions within the vanadophore is not clear. The difficulty arises because of the fragility of the vacuoles and because of their instability towards oxygen. The vacuoles lyse readily in distilled water to give a dark red-brown haemolysate with a pH of 2.5. Known as Henze solution it is presumed to contain vanadium in the trivalent state. When neutralised the solution turns deep blue, possibly by oxidation to form the vanadyl ion, VO^{2+} . In Henze solution the vanadium is bound to a protein termed homovanadin and to a small organic nitrogenous ligand (Bielig, H. J., *et al.*, *Protides Biol. Fluids*, **14**, 197; 1966). It was hypothesised that in the intact vanadophores the vanadium is likewise bound to a protein and small ligand. Now Carlson (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 2217; 1975) has re-examined the problem using proton NMR spectroscopy to probe the vanadium ion within intact vanadophores of the tunicate *Ascidia ceratodes*. Since lysing of the vacuoles offers the opportunity for oxidation, denaturation and artefact formation in the haemolysate it is an advantage to be able to probe the metal ion *in situ*.

The NMR spectrum of whole blood cells exhibits a broad 21-p.p.m. downfield, Gaussian signal which disappears on cell lysis. By comparison of this signal with the sharper signal, also at 21 p.p.m., found in 0.72 molal solution of vanadium (III) chloride in 0.5 M perchloric acid the signal is attributed to vanadophore water protons in rapid exchange with the protons of the water in the co-ordination sphere of vanadium inside the vacuoles. Coupled with the intensity of the signal the broadness argues against the signal being due to protons of a stable vanadium (III) complex. Carlson further points out that as the 21-p.p.m. signal decreases in amplitude and shifts upfield on lysis simple dilution is not occurring but rather oxidation and/or complex formation with a high molecular weight material. He also attempts a quantitative estimate of the vanadium (III) molal concentration by comparing the bulk resonance shifts of water in the spectra

of suitable vanadium (III) standard solutions with the magnitude of the 21.5-p.p.m. signal. This leads to a figure for the amount of vanadium accounted for by the 21-p.p.m. signal and, knowing the total vanadium content from atomic absorption studies, the maximum number of vanadophore vanadium (III) co-ordination sites interacting with ligands other than water *in vivo*. The conclusion is reached that a maximum of one co-ordination site per vanadium (III) ion is left available for binding an organic ligand. This view of a partially complexed vanadium (III) ion within the vanadophore is not in complete agreement with the views advanced earlier by Bielig.

Reviewing the function of the vanadium vacuole in the light of his recent work, Carlson proposes that the vanadocytes have properties not shown by the haemolysate, the system usually studied. It may even be necessary to regard the vacuole as the smallest functional unit. Carlisle (*Proc. R. Soc.*, **B171**, 31; 1968) has shown that intact tunicate blood cells act as oxygen storage and transport units although the blood haemolysate does not oxygenate reversibly. Carlson's work suggests a way out of this apparent contradiction. Further probe studies of the intact vanadocytes will be of great interest. Measurement of the electron spin resonance spectrum and the electronic spectrum using microspectrophotometry are two obvious techniques.

Beyond this, ascidians should have an increasing fascination for chemists in their search for biological functions of metals beyond the first transition series. In his 1968 review, Carlisle reports that many other metal ions besides vanadium are actively accumulated by different species of marine animals, for example, "titanium, chromium, manganese, iron, niobium, and tantalum, certainly, and possibly also molybdenum, zirconium, and tungsten. In all the animals investigated the metals are found in blood cells . . . associated with acidic conditions in which they exhibit a powerful reducing action." It is well known that at low pH the early transition metal ions will condense to form polymeric oxy-anion clusters but only in their higher oxidation states. Goldberg (*Mem. geol. Soc. Am.*, **67** (Treatise, 1), 345; 1957) has shown that these metals are actively accumulated since a lifetime of passive filtration could not pass sufficient water through ascidians to yield the levels which have been reported. The enrichment factors he quotes are spectacular. For example, for marine organisms by dry weight over seawater, titanium is enriched 10,000-fold, vanadium 280,000-fold and niobium 98,000-fold. Very little of the chemistry of these

processes is understood although in future the technological and environmental importance of such scavenging of metal ions will undoubtedly increase.

Hill reaction in the mountains

from Peter D. Moore

WHEN Turesson began his classic work on development of ecologically adapted races within species (*Hereditas*, **3**, 211; 1922), he paved the way for what has proved to be a profitable interaction between genetics, ecology and, more recently, biochemistry. In the early days of such studies, genetic strains could be detected only by structural variation, but recently it has become possible to document more subtle, physiological adaptations to differing environmental circumstances within certain species. Particular attention has been paid to temperature optima of selected biochemical systems from species at different altitudes or latitudes.

A system that has been investigated in several species is the Hill reaction of photosynthesis. This process, which is observed in isolated chloroplasts, when illuminated, involves the movement of electrons from water to an added chemical oxidant (such as potassium ferricyanide) against the chemical potential gradient. The reaction involves the production of oxygen, a process which is thereby demonstrated to be separable from carbon dioxide reduction in photosynthesis.

In 1968, Tieszen and Helgager (*Nature*, **219**, 1066) described experiments with populations of the grass *Deschampsia caespitosa* from arctic (Alaska) and alpine (Colorado) habitats. They measured the response of the Hill reaction (as ferricyanide reduction) to a range of temperatures and observed that the optimum for reaction was approximately 10 °C higher in the alpine population than in the arctic one. This appears to be related to the environmental conditions in the two habitats, for the alpine site would have higher daytime temperatures, whereas survival in the arctic conditions would be favoured by maintained activity even at low temperature. As with the work of Mooney and Billings on *Oxyria digyna* (*Ecol. Monogr.*, **31**, 1; 1961) a degree of flexibility was found if growth conditions were varied, particularly in the alpine population.

May and Villarreal (*Photosynthetica*, **8**, 73; 1974) subsequently examined the Hill reaction in populations of *Taraxacum officinale* from three different alti-

tudes in the Rocky Mountains of Colorado. When assayed at 15 ° and 25 °C populations from high altitudes (3,550 m) had the greatest rate of Hill activity. The reverse was true at 35 °C when the material from the highest site was virtually inactive. The authors suggest that the high rate of the Hill reaction in the elevated sites is an adaptation for fast growth during the short alpine season. This is coupled with a lower temperature optimum at the alpine site. This presupposes that the selection pressure for rapid growth is greater at high altitude than at low altitude. This is conceivable since other pressures, perhaps involving seed production and competition during establishment, may be more significant at lower altitudes. It would be interesting to couple these biochemical investigations with studies of the population biology of these plants in the vein of Gadgil and Solbrig's work on *Taraxacum* (*Am. Nat.*, **106**, 14, 1972). It would be of value to know whether the populations examined had been subjected to predominantly r and/or K selection within their respective habitats, for this could determine the relative survival value of rapid growth.

May and Villarreal collected their material from the field and analysed it within 4 h. They were not able, therefore, to conduct experiments in which growth conditions were varied and in which phenotypic acclimation could be separated from genotypic adaptation. In addition, the apomictic breeding system of *Taraxacum* makes it difficult to know how many separate genotypes are involved in these experiments. It has been demonstrated, however, that even in out-breeding species, such as *Abies balsamea*, the temperature optimum for growth varies considerably along altitudinal gradient (Fryer and Ledig, *Can. J. Bot.*, **50**, 1231; 1972).

It would be unwise to extrapolate from these data to make predictions for other species, however, as the results of Williams, Lazor and Yourgrau (*Photosynthetica*, **9**, 35; 1975) demonstrate. They have taken samples of *Verbascum thapsus* from several latitudes (30°, 47° and 51°) in the United States and also at several altitudes within the same latitude (in Colorado, of course). In contrast to the results of previous workers, they found that the high altitude populations had lower rates of Hill activity and there was no clear cut difference in temperature optima. In their latitudinal studies they found that low latitude populations showed higher activity than those of high latitudes. Thus the negative relationship between Hill activity and length of growing season shown by May and Villarreal for *Taraxacum*, does not hold for *Verbascum*. The very broad range of temperature over which *Verbascum* is

capable of maintaining high rates of Hill reaction is a notable feature of these studies. This could contribute to the success of this species as a weed of disturbed habitats in North America as well as in Europe and many other parts of the world.

Two main points emerge from these pieces of work. First, differences in Hill reaction rate and differences in the temperature optima for Hill activity exist between isolated plant populations, and there is evidence suggesting that these differences are genetically based. Second, it has become apparent that further advances in the understanding of these processes can only be achieved by making use of controlled environment growth experimentation. This is needed to differentiate between genetic and phenotypic adaptation within test populations and to document changes which may occur in the rate of Hill reaction with season or with advancing physiological age of the tissue being tested. □

Large scale shell model calculations

from N. MacDonald

A meeting on Large Scale Shell Model Calculations was held in Glasgow on August 27-29.

THE shell model plays a major role in the understanding of nuclear structure. Most of the particles in the nucleus are treated as inert, while the remaining few active particles are, to a lowest approximation, treated as moving independently in a common central potential. This approximation does not get one very far, and one calls on an effective interaction between pairs of active particles.

Two essential questions are thus raised. One is how to devise an effective interaction that can be related to the known features of interactions between free nucleons. The other is how many of the particles are to be treated as active, and how many states are to be regarded as accessible to them. About three years ago a substantial advance was made in handling moderately large numbers of particles. The technical problem involved is that of diagonalising very large matrices. R. Whitehead recognised that the key to this lay in the revival of the Lanczos algorithm, an iterative method involving repeated multiplication of an arbitrary vector by the matrix. When the vector has the form of a shell model wavefunction and the matrix

is that representing the two-body effective interaction, this iteration can be performed without ever storing the elements of the matrix.

The Lanczos method is the essential feature of the Glasgow shell model code, which has been used for very complete surveys of the nuclei from mass 17 to 39, over which the active particles fill the s-d shell. The meeting was held to review the progress made in these surveys, and the status of the shell model generally.

B. Barrett (University of Arizona, Tucson) reviewed the theory of the effective interaction. The problem is to go from a known interaction and a large set of states to an interaction yielding a good approximation when restricted to a much smaller set. The method used is perturbation expansion. Convergence is controlled by the extent to which states of the excluded part of the large set overlap in energy with those of the small set. For the s-d nuclei these intruder states undoubtedly lie at embarrassingly low energy. More sophisticated ways (double partition) of dividing up the large set of states may yet yield an effective interaction with a sound foundation, but at present shell model calculations are best tackled in a less ambitious spirit.

This means starting from a subset of the available data on a range of nuclei and determining the interaction that fits this best. Then one can test it on the remaining data. This process can start from a simple form of interaction, as in work on the s-d shell reported by P. W. M. Glaudemans (University of Utrecht) and other Dutch workers, who start from a surface delta interaction. They vary seven parameters to provide a preliminary estimate, and then carry out an iterative variation process on all 63 matrix elements. One may instead elect to vary all the two-body matrix elements without any constraints. The most ambitious attempt of this kind was reported by B. H. Wildenthal (Michigan State University). He used the Glasgow code in an unsuccessful attempt to locate such a best fitting interaction to data from the whole shell. Failing this, he was able to provide separate interactions for the upper and lower halves of the shell. These supersede the earlier Michigan interactions found by fitting data over smaller sets of nuclei with the Oak Ridge codes.

The next step into larger spaces, as for example nuclei of mass 40 to 70, goes beyond our present powers of computation. It becomes essential to truncate the space used. It was hoped that with the Glasgow and Michigan results for the s-d shell one might be able to devise a trustworthy truncation scheme. One approach reported by

P. Manakos (University of Darmstadt) and J. Millener (Oxford University) uses the SU3 scheme, which relies on the approximate validity of certain symmetries in nuclear states. Another (J. Morrison, University of Glasgow) is to employ a deformed rather than a spherical common potential. A danger which emerged in studies of truncation, in particular in those reported by A. Watt (University of Glasgow), is that the best strategy may depend very much on the interaction used. But in any higher shell the interaction may be quite different from those used in the s-d shell. A consolation is that in studying this question one learns quite a lot about the nature of the states ground out by the mammoth computations.

The most mysterious feature of the Lanczos method in its nuclear applications is the extremely rapid convergence of the iterations. Almost independently of the size of matrix, 50 to 100 steps suffice to get the desired low states. R. Whitehead (University of Glasgow) presented various results related to this. One is the formal relationship, by way of the technique of Pade approximants, between the Lanczos method and the inverse iteration method. Another is that performing 50 multiplications by the energy matrix, starting with an arbitrary vector, is related to evaluating the first 50 moments of the energy in an arbitrary state. Techniques for studying low moments, which were discussed by O. Bohigas (Orsay), could conceivably be extended to approach the shell model in a different way. □

European earth scientists seek closer collaboration

from A. J. Smith

The meeting of European Geological Societies (MEGS) organised jointly by the Geological Society of London and the University of Reading was held at Reading from September 8 to 12.

THE theme of the meeting, which was attended by about 400 earth scientists, was 'Europe from Crust to Core', and early announcements expressed the hope that geologists and geophysicists "would discuss the crucial scientific and socio-economic questions affecting European geology in the next 100 years". The programme promised that the theme and ideal might be achieved and in the event, thanks to excellent organisation and a warming by those

present to the concept of a collective European image, the promoters can feel well satisfied. In their opening remarks Sir Kingsley Dunham (Institute of Geological Sciences, London) and P. Allen (University of Reading) urged participants to cross political and disciplinary boundaries for the benefit of geological science, Europe and the rest of the world, a theme to which J. M. Harrison (UNESCO, Paris) returned on the closing day of the meeting.

The programme was built upon Stille's concept of Europe's crustal framework, with thirteen keynote addresses, numerous shorter contributions and ample time for formal and informal discussion. The opening keynote address by V. E. Khain (Moscow State University) was concerned with the new tectonic map of Europe which is to appear in 1977. He reviewed the wealth of geological information which has become available since the production of the first tectonic map of Europe less than a decade ago. Both he and Janet Watson (Imperial College, London), in her address on the evolution of the European craton, drew attention to the strong influence of a Precambrian framework on the succeeding development of the European crust. Major structural lines, once started, have reasserted themselves and influenced succeeding events. Other keynote speakers and contributors made clear that ocean floor spreading did not offer a panacea for Europe's lithospheric history and, instead, that gravity tectonics, often along old lines, frequently offer a more satisfactory explanation. A. Kvale (University of Bergen) pleaded for more work to increase the scientific value of plate tectonic models applied to the European Caledonides, while W. Krebs (Braunschweig Technical University) questioned the existence of any Palaeozoic 'oceanic' crust anywhere in central Europe, preferring the concept of repeated metamorphism and plutonism caused by ascending mantle diapirs. H. Ramberg (Uppsala University), Krebs and many others saw the driving force of folding, thrusting, allochthonous gliding and nappe transport as resulting from the potential relief energy between rising zones and synchronously subsiding adjacent troughs. Sir Peter Kent (Natural Environment Research Council), dealing with new knowledge from the North Sea, drew attention to the relationship between freer movement of plates in North-western Europe from mid-Cretaceous times consequent on the parting of the crust in the Atlantic replacing the stretching of marginal continental crust. He also drew attention to the need for a reappraisal of accepted theories for the origin of the Permian evaporites. A. Aubouin (Université

Pierre et Marie Curie, Paris), in his summary of the Alpine orogeny of the eastern Mediterranean, while accepting the 'classical' plate tectonic approach, though without the need for entrapped microplates in the eastern Mediterranean, stressed the need for more work to explain the numerous enigmas. E. Niggli (University of Berne) instanced the problem of the depth of crystallisation of blue schists and the possibility of tectonic stripping of cover.

Geophysical topics concerned with the deepest crust, mantle and core naturally ranged beyond the limits of the European continent. Several geophysicists drew attention to the contrasting crustal thickness between adjacent European areas—the non-sedimentary crusts beneath Cainozoic depressions being some 30 to 45% less than beneath the Hercynian massifs.

Many speakers stressed the role of the geologist as a forecaster as well as a recorder of events. G. F. Mitchell (Trinity College, Dublin) made much of this in his Quaternary review, as did M. Arnould (Ecole National Supérieure, Paris) and G. Luttig (Geological Survey, Hanover, FDR). Geothermal energy, the disposal of radioactive wastes, environmental and conservation topics were discussed in the European context. Speakers both in the main conference and at the meet-

A hundred years ago

IT is rather disappointing that Capt. Young's Arctic Expedition in the *Pandora*, which arrived at Portsmouth on Saturday, should have returned home prematurely without accomplishing any part of the work for which it was organised—the discovery of additional Franklin relics and the complete navigation of the North-west Passage. Under the circumstances, however, Capt. Young has adopted the wisest possible course. Better that the expedition should spend a comfortable winter at home, and set out early next year to renew the attempt in which they have just been baffled. Disco was reached on August 7, Upernivik on the 13th, and Cape York on the 16th, after a splendid passage through the much dreaded Melville Bay. Carey Islands were visited to deposit letters for the *Alert* and *Discovery* and to obtain a despatch from Capt. Nares, as previously agreed on. The despatch, however, was not discovered till the return voyage.

From *Nature*, 12, 539, October 21, 1875.

ing of the Commission on the Tectonics of Ore Deposits, which met concurrently with MEGS, described the value of ERTS (Earth resources technology satellite) imagery in a greater understanding of Europe's structure and in the search for mineral resources. Pleas that geologists generally should pay more attention to the special needs of engineers and planners were common, and the need for more mathematical, chemical and experimental approaches to earth science was examined.

European geologists were reminded of their obligation to the rest of the world in more than just an economic sense: G. Jenkins (University of Canterbury, Christchurch, New Zealand) reminded them that stratotypes, the key to the worldwide geological division of time, were often first described in Europe, and that to aid worldwide

correlation more must be researched in Europe and published.

A perhaps oversimplified view of the meeting might be that extremely useful summaries of the state of European geology were given, showing that Europe still presents fundamental questions in need of answers. Seeking such answers can occupy European geologists, geochemists and geophysicists for a long time to come. Time, particularly in respect to resources, will not wait for geologists any more than for the rest of mankind, and the participants recognised that closer collaboration between European earth scientists is urgently needed.

About a year ago correspondence in *Nature* referred to MEGS under the heading 'European earth scientists disunite', suggesting that a schism had opened between European 'geologists' and geophysicists. In this context it is

a pity that so few geophysicists attended MEGS for they would have enhanced the meeting. The Reading meeting showed that European earth scientists sincerely desire to act in concert for the benefit of Europe and the world. The UK initiative which created MEGS was warmly appreciated. The establishment of a European Geological Society was discussed and received wide support but no final decision was reached. Instead it was decided to set up an interim committee composed of representatives of a number of the participating countries to promote a MEGS 2 (representatives of both the Netherlands and France indicated a desire to host such a meeting), to cooperate with existing international and European bodies and to encourage closer communication between European earth science societies. □

CONTRARY to widespread belief, although the steady state theory of the Universe may be dead it refuses to lie down, and a small band of enthusiasts continues to try to breathe life into the presumed corpse. But the chances of a miraculous resuscitation do not look too good, as the appearance of two papers together in the same issue of *Mon. Not. R. astr. Soc.* shows. In one of these contributions (172, 623; 1975) P. K. Das of the Tata Institute develops further the model of QSOs as compact, highly gravitationally redshifted objects that he and J. V. Narlikar put forward recently (*Mon. Not. R. astr. Soc.* 171, 87; 1975); although Das does not mention the steady state theory, it seems a reasonable assumption that any colleague of Narlikar's who discusses possible non-cosmological contributions to the redshifts of QSOs has the concept not too far towards the back of his mind.

This model has a great deal of interest for theorists and students of relativity, whatever its application in the real Universe, and consists of a static, spherically symmetric distribution of a mass M in a radius R (Das uses dimensional units), in hydrostatic equilibrium, obeying Einstein's equations and divided into two regions, core and envelope. The earlier paper from Das and Narlikar developed equations for the isothermal core-adiabatic stable envelope configuration and discussed some implications for redshifts; in his new work Das concentrates on a discussion of how light propagates from both the surface and interior of such an object, and the effect of this on the angular diameter seen by an external observer.

The observed features of such an object depend on whether R is greater

One step forward and two back for the steady state

from John Gribbin

than or less than $3M$, and the ratio R/M is reduced by 'stiffening' either the core or envelope, that is, making the model more relativistic. For light emitted from the surface, as the core or envelope equation of state is stiffened the angular diameter decreases from its Euclidean value; for sufficiently stiff core-envelope combinations, the back of the source becomes visible, with the entire surface eventually being mapped into a thin ring.

But the source need not appear as a ring, and light emitted from the interior can play a part in determining the overall appearance. Combining the effects on light from the core and from the surface with the earlier investigation of redshifts, Das is able to produce an angular diameter-redshift ($\theta(z)$) relationship. He finds that as the core-envelope combination is stiffened a plot of θ against z shows a minimum, which shifts to higher z as the stiffening increases, and "it is interesting to note that θ calculated on the basis of cosmological redshift hypotheses also shows a minimum at comparable values of z ".

The properties of this model do depend critically on the equation of state, and for pressure as high as half the energy density the angular dia-

meter is constant irrespective of surface area, with multiple imaging taking place. Of course, radiation from the interior will be absorbed by intermediate material *en route* to the observer, and investigation of the expected absorption feature is the logical next step in developing this intriguing model. Intriguing though it is, however, it is a little artificial, and its relevance to the real world must be in even greater doubt in view of the paper by V. K. Kapahi (ironically, also of the Tata Institute) in the same issue of *Mon. Not. R. astr. Soc.* (172, 513; 1975). He has looked at angular size counts of extragalactic radio sources, using the 3CR catalogue, and finds evidence of evolution in source properties even when QSOs are excluded from the sample. This is already difficult to reconcile with steady state ideas, and the same sort of evolution also seems to be present when QSOs are analysed separately, which suggests rather strongly that QSOs really are part of the same family as other extragalactic radio sources.

The best explanation of these variations is to fit them to a simple Einstein-de Sitter cosmology in which the local radio luminosity function (RLF) steepens considerably at high luminosities, the comoving density of high luminosity sources increases with z in a manner similar to that implied by number-luminosity ($\log N - \log S$) studies and the V/V_m test for QSOs, and mean physical sizes of radio sources evolve with z approximately as $(1+z)^{-1}$. This important confirmation of the pattern suggested by the earlier studies hints strongly that even if a way can be found of mimicking QSO properties in other ways, the cosmological interpretation stands better than ever before. □

Computer supplement

How Babbage's dream came true

M. V. Wilkes

Computer Laboratory, University of Cambridge, Cambridge, UK

Charles Babbage dreamed up a form of computer in the 1830s. His ideas lay dormant until digital machines became a reality in the 1940s. Professor Wilkes, one of those responsible for the implementation of the digital computer, describes some of the prehistory and early history.

COMPUTERS have a history and a prehistory. If we confine ourselves to electronic computers the first historical date in the computer era is February 18, 1946 when the ENIAC was formally inaugurated at the Moore School of Electrical Engineering in the University of Pennsylvania. Nine months earlier, in May 1945, the Automatic Sequence Controlled Calculator had been set going at Harvard University. It was not an electronic machine but was based on the use of rotating shafts, electromagnetic clutches, relays, and so on. It had, however, the distinction of being the first fully automatic digital computer to be completed. Its origins can be traced back to a report written by Howard H. Aiken in 1937. The machine was built by International Business Machines (IBM) with Aiken's vigorous co-operation. A number of machines using telephone relays for computing purposes were built. As early as 1938 there had been interest in this subject at the Bell Telephone Laboratories and a number of special purpose devices had been built and used. This work, however, did not culminate in the construction of a completely automatic calculating machine until 1946. Zuse also worked on relay computing devices in Germany during the latter part of the war. Randell¹ provides documentation of this period.

The prehistory of the subject formed the life's work of just one man, Charles Babbage (1792–1871). Although he never completed his machine Babbage had all the ideas and L. J. Comrie when writing for *Nature* a review of a book describing the Automatic Sequence Controlled Calculator had the happy thought to entitle it "Babbage's Dream Comes True". I have adapted this title for the present article.

Babbage began to think about calculating machines in about 1812 or 1813 at a time when he was still a student at Cambridge. His interest had been caught by a very ambitious project for computing mathematical tables started in France during the time of the first Republic. The principle adopted in this project was to compute accurate values at rather widely spaced values of the argument, and to produce values at the required tabular interval by systematic interpolation or subtabulation. Babbage saw that this could be done by a machine which he called the Difference Engine. Not only would this have calculated tabular values, but it would also have prepared the moulds from which stereo plates for printing could be cast. This was an important point and Babbage thoroughly appreciated the importance of avoiding copying and typesetting errors.

Babbage became very enthusiastic about the Difference Engine and successfully communicated his enthusiasm to the

British Government, who gave him financial support. All went well to begin with and he spent a number of years happily engaged in supervising the construction of the engine. Unfortunately, however, a high rate of progress was not maintained and difficulties arose between Babbage and his engineer. Eventually the project had to be abandoned without there being anything to show for it.

Babbage's mind was, however, working on generalisations of the Difference Engine and suddenly around 1834, when he was 42 years old, he began to perceive how a truly general purpose calculating machine could be made. One idea followed another in rapid succession. On September 18, 1834, he wrote to his close friend John Herschel, the astronomer, who was then working at the Cape of Good Hope: "I have begun to criticise all I have done and to consider it merely as the bricks of a better fabric. In the first place I have simplified and can, therefore, again generalise. . . . In short I see my way on towards turning the whole of analysis into wheel work as far, at least, as numerical results go, and this will at last come"². The intellectual excitement that Babbage was experiencing at that time is well brought out in an earlier letter to Herschel: "I suppose like myself you have never one hour out of the twenty-four to spare; yet I should like, if possible, to catch one to discuss with you some of the *stray* questions about which I cannot resist indulging myself as a refreshment from the Analytical Engine"³. He goes on to mention several topics, such as the theory and practice of cutting tools, how to make a real automaton, and so on.

The machine that Babbage named the Analytical Engine was—or would have been had it been built—a true, automatic digital computer. Like a modern computer it was to have a store in which numbers could be held, and a processor known as the "mill" in which the arithmetic operations would be performed. For the control of the calculations, Babbage at first proposed to use a drum with moveable studs, but almost at once he took the important step of deciding to adopt the Jacquard mechanism that had then come into general use for controlling looms. His ideas developed very rapidly and by the end of 1837 he had drafted an account setting them out in some detail. For the rest of his life Babbage worked on the design of the Analytical Engine, improving and refining his ideas, but his account of 1837 contains all the essentials (see ref. 1).

For some reason or other Babbage did not publish this account; in fact there is very little in his published writings about the detailed way in which his ideas would be implemented. He described the functions of the store and the mill, but he did not even introduce a term to describe what we would now call the control unit. A good deal of information was, however, published about the general principles on which the Analytical Engine worked and the type of calculation for which it could be used. In 1843 Babbage gave a series of presentations in Turin. An account of these was written by Menabrea and published in a Swiss journal. The paper was translated from

the original French by Lady Lovelace who added extensive notes, written under Babbage's close supervision. The idea of repetitive loops within a calculation was explained, but the actual way in which they were set up was not described. Lady Lovelace gives a number of what appear to be programs, but close examination shows that only the arithmetic operations are described; the repetitions are indicated by comments or by statements in the text that certain series of operations are to be repeated so many times. Babbage proposed to use separate Jacquard mechanisms to control operations and variables; these would step independently and go through independent cycles. For some reason he never arrived at the idea, so familiar to us, of an instruction consisting of an operation code associated permanently with one or more addresses. It is, however, clear from his notebooks and other unpublished writings that he gave very detailed thought to the sequencing mechanism⁴. Associated with each Jacquard mechanism he proposed to have a "card counting apparatus" or "repeating apparatus". This

Charles Babbage (1792–1871)

Let it be granted that in his life there was much to cause disappointment, and that the results of his labours, however great, are below his powers. Can we withhold our tribute of admiration to one who throughout his long life inflexibly devoted his exertions to the most lofty subjects? Some will cultivate science as an amusement, others as a source of pecuniary profit, or the means of gaining popularity. Mr. Babbage was one of those whose genius urged them against everything conducive to their immediate interests. He nobly upheld the character of a discoverer and inventor, despising any less reward than to carry out the highest conception which his mind brought forth. His very failures arose from no want of industry or ability, but from excess of resolution that his aims should be at the very highest. In these money-making days can we forget that he expended almost a fortune on his task? If, as people think, wealth and luxury are corrupting society, should they omit to honour one of whom it may be truly said, in the words of Merlin, that the single wish of his heart was "to give them greater minds"?

From W. S. Jevons's obituary notice of Charles Babbage (*Nature*, 5, 28–29; November 9, 1871).

would be loaded with an integer which would be decremented whenever a card was read. When the counter liquidated ('running up' was Babbage's term) an appropriate action would ensue. Babbage is not anywhere fully explicit about how the system would work and I doubt if he ever entirely made up his mind between the various alternatives. He proposed to systematise the internal control by making use of "barrels", or drums with projecting studs, a system that offers a striking parallel to microprogramming.

Reading Babbage makes one realise what an important advance was the development of the modern concept of a program as something which can exist as a valid statement of an algorithm independently of the computer on which it will run and about which things may even be proved. Part of the breakthrough of the stored program computer was the development of a language—initially machine language only—in which programs could be written. If Babbage had described in formal terms the role played by his card counting apparatus and had introduced a notation for the way in which the Jacquard cards were punched, he might have taken this vital step; however, the fact that he had independently stepping Jacquard mechanisms to control operations and variables would have made the programs difficult to follow, and they would not have borne much resemblance to modern programs.

One must ask why, in the end, Babbage had so little to show by way of practical achievement. I think that he might well have hoped to finish the Difference Engine. The ideas were sound enough, as was shown by the fact that another implementation of them, by George and Edward Sheutz, was successful; however, that was a good deal later, in 1855, and the techniques of mechanical engineering were developing rapidly at that period. Much of the responsibility for the failure of the Difference Engine must fall on Joseph Clement, whom Babbage employed to be in charge of the construction. In April 1828 Herschel, who was looking after things during Babbage's temporary absence in Italy, clearly thought that the progress being made was inadequate in view of the amount of money being spent. At that time Clement was employing 10 people on the project⁵. Babbage, however, continued to have full confidence in Clement and it was not until five years later that they finally fell out.

The Analytical Engine was another matter. I doubt if it would have been possible for Babbage to have produced a full scale machine that would work at all reliably. To do so using the mechanical principles he had in mind would be far from easy today. In view of what had happened to the Difference Engine, there was little prospect of his getting the necessary financial support to set up a proper project. Babbage was, however, prepared to spend his own money and always had people in his employ; after his death his younger son carried on the work for some time. As a result many drawings were made and some pieces of the Analytical Engine were constructed; these are now to be seen in the Science Museum at South Kensington.

Babbage's real achievements were intellectual, and they remained buried in his notebooks. In March 1839 he did indeed draft a plan of a work entitled *The Science of Number Reduced to Mechanism*⁶. He revived this project at various times and it is hard to see why he did not persevere with it, particularly since he was an accomplished writer and published extensively on other subjects. If he had done so he might well have shown the way for someone else to put his ideas into practice. As it was they were lost and what was of value in them had to be re-discovered.

We must, I think, conclude that, although a mathematician and a man of science, Babbage was, as far as calculating machines are concerned, an inventor at heart. That is to say he saw achievement in terms of the successful construction of a device and not in terms of the publication of ideas. Inventors are vulnerable to the hazards of the world and as likely as not end by becoming bitter and disappointed men. Babbage had more than a twinge of such feelings, but fortunately the Analytical Engine, although it occupied a large part of his life, was not his sole preoccupation. His other interests were wide and varied

and he led an active social life. He could be tiresome and self-important, but he had many friends and was by no means lacking in humanity, as anyone reading his autobiography will appreciate.

When I became interested in computing in the years immediately before the Second World War, L. J. Comrie and others were showing great ingenuity in using commercial accounting machines for scientific purposes and they took great delight in exploiting their special features in new ways. The climate of opinion was, however, distinctly hostile to the production of special digital machines for scientific calculation, either by the adaptation of commercially available machines or otherwise. On the other hand, various analogue devices were coming along; these included the differential analyser, announced by Bush in 1931, and various linear equation solvers. The scientific world was prepared to give these a sympathetic reception and it suffered the inevitable disappointment. In fact, when the EDSAC began to work in Cambridge, one of my tasks was to persuade people that it was not like another analogue device with its own esoteric techniques, but that it handled proper numbers in the proper way. Fortunately, I was helped by the fact that the second program run on the EDSAC was one for the listing of prime numbers, something manifestly respectable from an arithmetic point of view.

The EDSAC began to work in May 1949 and other early computers came into operation at about the same time. These were the first stored program computers—the ENIAC had been programmed by means of a system of plugs and sockets and switches—and the development of the new subject of programming then became possible. As might be expected, different groups followed their individual ways and there was a good deal of diversity. That was not only because the computers had their own instruction sets but also arose for more or less accidental reasons connected with the background and attitudes of the staffs involved. Computer peripherals were in a primitive state of development and the capabilities of a computer were much coloured by what it happened to possess in this respect. This was particularly true because all the early computers had very small high speed memories. The Pilot ACE at the National Physical Laboratory (NPL), for example, used punched cards for input and output, and it was possible to punch 12 binary numbers on a card, one on each row. Punched cards could thus be used as an auxiliary memory and the machine was very suitable for performing matrix calculations. The NPL, therefore, took a lead in that aspect of computing, with consequences that remain to this day. In Cambridge we had punched paper tape for input and output, and a mechanical read-only memory from which a set of initial orders could be copied into the high speed memory to control the reading of the program tape. We were, therefore, led to develop a format for instructions that may be regarded as the forerunner of later assembly languages. At Manchester, they had a magnetic drum as well as a high speed memory from the very beginning, and they therefore developed methods of programming that exploited a large auxiliary memory earlier than the rest of us. This diversity was very helpful to the development of the subject, and we all learnt much from comparing notes. Those who were active in the small computer world of the late 1940s and the 1950s will remember the regular colloquia held in Cambridge on certain Thursday afternoons, which provided a good opportunity for the experts to compare information. They also served the purpose of those who wished to inform themselves about what was going on at a time when published material was scarce and contact with one or more of the established centres was essential.

It came as a surprise to me personally to find that it was so difficult to get programs right. In Cambridge there was much emphasis both on programming aids to debugging and on methods of constructing programs that would be relatively fool-proof. The use of previously tested subroutines was one such method, and we recommended the construction of a program by means of nested, closed subroutines with program para-

meters; if one substitutes the words 'procedure call' for 'closed subroutine', we have here one of the central tenets of structured programming. A consequence of the adoption of these methods was that we found little need to draw flow diagrams, and I have always felt that the motto on the structured programming banner should be "flow diagrams considered harmful".

Along with the development of programming techniques went the development of computer applications. An early problem to be solved on the EDSAC was one proposed by R. A. Fisher⁷. He wrote to me early in 1949, before the EDSAC was working, saying in characteristically barbed fashion that he understood that our fine new machine was not going to be used only for wave mechanics and that he would like to have a numerical solution of a certain second order nonlinear differential equation with two point boundary conditions. I do not think that he had much hope that we would produce the solution, but one was, in fact, obtained by D. J. Wheeler as part of his thesis work. Fisher was duly impressed and he eventually published the solution with a suitable acknowledgement.

Atomic calculations were, of course, an obvious field of application for an electronic computer, although we realised that the early machines would be somewhat lacking in capacity. I remember one day accidentally running into S. F. Boys at Imperial College. We had known each other in Cambridge before the war and he asked me what I was doing now. I told him about the EDSAC under construction and rather to my surprise he began to explain to me why such a machine would not be of any use for the type of atomic calculation that he was interested in. I kept my counsel, but later, when Boys had returned to Cambridge and became an enthusiastic user of the EDSAC, he was only too ready to confess how wrong he had been. The point that he had failed to grasp was that a digital computer could perform logical as well as arithmetic operations; the EDSAC had one order for performing a logical operation, namely, that of bit by bit Boolean multiplication of two binary numbers. This was known as the 'collate' order and Boys found that it made all the difference.

I was more than willing to tell people about the EDSAC, but I never made any attempt to sell them the idea of using it if I met with sales resistance. To do so was unnecessary since there was no shortage of users. At first, professional programmers did not exist and people had either to learn to do their own programming or persuade someone who was working with a machine to do it for them. Our own research students were the best ambassadors. Computer applications in X-ray crystallography were pioneered in Cambridge by J. C. Kendrew, then a junior member of the staff of the Cavendish Laboratory, and J. M. Bennett, a research student with us. This led in due course to the calculations for the structure of myoglobin that were done on EDSAC 2. It was through contacts of this kind that the use of a digital computer spread in Cambridge, and I am quite sure that the same is true of other places.

In the very early days it was possible for the management of a computer centre to follow in some detail what all the users were doing. We had in the laboratory a body known as the Priorities Committee before which all applicants for computer time would appear to explain their problem. In spite of its name, the Priorities Committee was essentially a technical committee, and the members would discuss with the applicant the best way to go about his work, the best numerical procedures to use, and so on. From time to time, the applicant would come back to tell the committee how he was getting on. I found these regular meetings of great interest, since they brought me into touch with a wide and ever expanding variety of subjects, as more and more research workers realised that a computer could be of assistance to them. In the course of time, much of the work of the committee became routine, but it still continued to discuss the more interesting projects.

I have mentioned that one of the very early programs to be run on the EDSAC was one for listing prime numbers. This particular program worked by the crude method of dividing each odd number in turn by all the odd numbers not greater

than the square root. The division was done by repeated subtraction since the EDSAC had no divider. It took about 10 minutes to compute and print the first 170 primes. Wheeler later wrote a program that was essentially a mechanisation of the sieve of Eratosthenes. The EDSAC had a cathode ray tube monitor on which the contents of the high speed memory could be displayed in raster form. It was possible to show 16 35-bit words at a time, that is, 560 bits altogether. In Wheeler's program the odd numbers were represented in order by binary digits. To begin with, all these digits were ones, indicating that all the numbers were present. As the sieve operated and numbers were eliminated the ones were replaced by zeroes. The speed of the machine was such that it was possible to watch this happening on the screen.

J. C. P. Miller, who joined the Laboratory at the beginning of 1950, had a long-standing interest in prime numbers and he and Wheeler set about seeing whether they could break the record for the largest known prime number. This was the Mersenne number, $P = 2^{127} - 1$, which had, some 75 years before, been shown by Edouard Lucas to be prime. Miller and Wheeler prepared a routine for testing the primality of numbers of the form $kP + 1$ and soon found ten values of k that gave prime numbers. On June 7, 1951 they wrote a letter to *Nature* reporting this fact⁸ and giving the largest known prime number as $934P + 1$. They added a note in proof (October 8) giving two even larger primes, the larger of which, $180P^2 + 1$, was the largest then known. They added that A. Ferrier, using a desk machine, had just demonstrated the primality of another large number, and that this was the second largest known prime. Though we were glad that the EDSAC had broken the record, we had much sympathy with Ferrier, who after great labour with a desk machine, had had the trophy snatched from his hands at the last moment by the march of technology. In another way we were fortunate. The prize, by all justice, should have gone to Manchester University, where somewhat earlier a baby model computer had been demonstrated. This was very limited in that it had no reader for punched cards or paper tape,

and no printer, and it could only perform the operation of subtraction; moreover, its memory was minute. Nevertheless, with great skill, a program for testing Mersenne numbers for primality was written, and quite a lot of numbers were tested. Alas, none of them were primes.

Ryle has related in his Nobel address⁹ how the development of radiotelescopes working on the principle of aperture synthesis depended on the availability of adequate computing power. I had a particular interest in anything to do with radio, since my own graduate work had been in the field of radio wave propagation and had been done at the Cavendish Laboratory. Pilot experiments in aperture synthesis were done with EDSAC 1 and EDSAC 2 and showed that a more powerful machine would be needed to handle routine reductions for a large telescope. Fortunately, such a machine was planned to come into operation in 1963 and I was glad to assure Ryle that the time would be available. When the telescope came into operation, there was a standing instruction in the laboratory that the routine reductions for it should have priority over all other work. In the ordinary way, this was not important, since the amount of time required was not great, but it did mean that, when the service was disrupted by maintenance or for other reasons, the telescope came first. It was one of Ryle's colleagues working on optical astronomy who made the remark in a lecture that the telescope was no longer the most important instrument used in astronomy, having been displaced by the computer. That was a clear exaggeration, but it showed what had been achieved in the space of a few years.

Whatever happened to the Stantec Zebra?

David Davies

University central computing needs in Britain are provided for by an increasingly unified set of machines. The next step is likely to involve more comprehensive networking.

BRITISH universities, with about 250,000 students, 40,000 of these at the graduate level, have roughly £58 million of capital equipment on their premises in the form of central computers, and the annual expenditure on hardware, buildings and recurrent costs runs at about £12 million.

Central policy on large computers is the concern of the Computer Board for Universities and Research Councils, which recommends action to the Department of Education and Science on university computing facilities; the board, under the chairmanship of Dr A. H. Chilver (Cranfield Institute of Technology) comprises eight members. It further gives advice to the research councils, although it has no control over their choice. It also reviews longer term policy on computers, which means these days that it does a fair bit of persuading universities that they will have to live with what they have

got for a year or two longer than expected. In the most recent report from the board (in August) broad hints were being dropped that university computers should have a lifetime of 10 years or more, "longer . . . than has been usual in the past". The problem the board faces is that much of its money is committed years in advance and any governmental squeeze is therefore difficult to apply in an even-handed way.

Time was when the university computer laboratory was a place where universities learnt how to build computers and research workers learnt how to operate them. Less than 15 years ago I can recall working in a computer laboratory where the staff used to leave a pile of chasses on the bench each night when they went home. If the machine went wrong, you ran a special program which produced a high pitched note through a loudspeaker. You took a mallet, banged the chasses one after the other, and when the pitch changed you knew you'd found the dud one, which you then replaced. The staff topped up the valves on the dud chassis in the morning.

All that has, alas, gone and in retrospect the turning point at which quirky originality had to be sacrificed to reliable uniformity was the publication in 1966 of the Report of the

Table 1 Recommendations of the Flowers report

University	Had in 1965	Flowers recommended	Has now
Cardiff	Stantec Zebra	Elliott 503	ICL 4/70
Sheffield	Mercury	ICT 1907	1907 and 1906S
Belfast	Deuce (borrowed from US Navy)	ICT 1905	ICL 1906S
Keele	(Private property of Professor McWeeny)	ICT 1903	ICL 4130
Leicester	Elliott 803	Add an Elliott 503	Cyber 72
Aberystwyth	IBM 1620	Elliott 4100	Two ICL 4130s

Flowers Working Group on Computers for Research. The group, charged with assessing university and research council needs for five years, found a wide diversity of incompatible machinery, most of it inadequate either in size or reliability for the burgeoning demands for computer time. The report correctly noted that many scientists were desperate for computer time—"Swansea will shortly be accessible from Aberystwyth only by private car, and that requires 2½ hours driving over mountain roads", "one man [at a London college] found it quicker to compute in Canada, flying there and back at frequent intervals", and so on. Remote terminals were only just coming in; Project MAC with an IBM 7094 at MIT was described admiringly.

Flowers urged that three very large computers be installed in London, Manchester and Edinburgh, which would serve as regional centres. Individual universities should have better computing facilities and compatibility with the regional computers. "The system would thus form an integrated whole." Some of the recommendations of the report are shown in Table 1. Expenditure was expected to be £20.5 million for universities over a period of five years.

The "very large machines" for the regional centres would have to be American. There was an interesting discussion in the report of the problems of keeping up with IBM, but it was clear that the IBM 360/92 and the CDC 6800 were the only real competitors.

The government accepted almost entirely the generous and detailed suggestions of the Flowers report; because of the "economic situation" it would take six years instead of five to implement the recommendations. The three regional centres were set up and a fourth, well equipped centre aimed at providing a focus for the universities in the south-west (Bath, Bristol, Cardiff, Exeter and the University of Wales Institute of Science and Technology—UWIST) is in process of being established at Bath (see Table 2). In addition other universities have been virtually re-equipped since 1966. A summary of computing equipment installed or ordered for all universities is given in Table 3. The Computer Board says, a touch laconically, "without any undue complacency, we feel the aims set out in Flowers Report have, to a large extent, been achieved".

What Flowers could not foresee, and what has added to the importance of the regional centres, has been the emergence of remote terminals as a way of life. Most universities are either on a network such as the South-West network, or possess Computer Technology Limited 'Satellite One's which for £20,000 put the universities in touch, by phone line, with a

Table 2 Equipment at Regional Centres

Centre	Equipment
Edinburgh	2 × ICL 4/75s; IBM 370/158; ICL 2980 (on order)
London	CDC 7600/6600/6400; Cyber 72
Manchester	ICL 1906A; CDC 7600; Cyber 72
Bath (not officially a Regional Centre)	2 × ICL 4/50s; ICL 2980 (on order)

regional centre. No more 2½ hour drives through the Welsh mountains; even the tiny and remote St David's, Lampeter now calls up Swansea on its Satellite One.

The health of British university computing is very much intermingled with the health of ICL; three-fifths of the capital investment is in ICL machines. The procedure for purchasing computers runs roughly as follows. For computers of power greater than one Atlas (the Atlas was a computer built in the 1960s; powers are measured by complicated assessments using benchmark programs) ICL may be invited to submit, singly, a tender. If, however, it is obvious that someone else can offer a cheaper and better machine over a shorter time scale the purchaser can go to open tender, but one of these tenders has to be from a British Company (which will be ICL). At the very large end (20 Atlas-power) ICL does not compete with the CDC 7600. But at 10 or so Atlas-power, the ICL 2980 in the 2900 range becomes competitive.

When ICL launched its new 2900 range in October 1974 it already had £21 million of orders, of which British universities had contributed £5 million. Ironically, when (shortly thereafter) the European Space Research Organisation (ESRO) ordered two 2980s they could only be supplied by persuading the universities to hold off for six months so that ICL could honour the ESRO contract.

Is the character of computing changing? In the past the regional centres were conceived as number-crunching establishments where immense calculations could simmer for hours on end. The number of scientists crunching numbers is not rising dramatically although, given half a chance, some of those who have contented themselves with one- and two-dimensional calculations would add an extra dimension. They are not likely to get that chance as the demand which is growing and which Flowers perceived in 1966 is for data manipulation. In such work the requirements are much more for easy accessibility of data bases, be they reference bases such as census results or dynamic bases such as meteorological conditions. There is little point in doing such operations down a telephone line, since the amount of data-shipping to interactive facilities may be colossal; the local centre comes very much into its own.

Ideally such data bases reside at the local computer, since they

Table 3 Equipment installed or on order at March 31, 1975

cost a lot to ship, but networking of a more comprehensive kind (such as Professor Kirstein describes in this supplement) is gradually becoming a serious alternative. The use of a network to distribute computing load is already explicit in the present phone-in arrangements to regional centres. The use of a network to handle a data base at a distance, or even a distributed data base in several parts of the country, requires further refinements; a scientist in Exeter must be able to handle a data base in Aberdeen by using programs resident in Aberdeen or even in East Anglia.

To this end several universities have expressed interest in using the Post Office's Experimental Packet Switching Service (EPSS) shortly to start operating and permitting data to be transferred at up to 48 kbits per second on a shared and sorted basis rather than by means of a continuous link. The eyes of the

more ardent data processors are bound also to turn towards the European Informatics Network, a project under the auspices of COST, the European Programme of Collaboration in Science and Technology. Ten nations are signatories to the project and at present five centres are to be joined by a packet switched network; the British link is through the National Physical Laboratory, Teddington. The network was not designed specifically for university use although universities in Milan and Zurich will be on it but it is possible that in the future it could be accessed through the EPSS to Teddington.

As far as bigger machines are concerned, there is little on the horizon. Sophisticated processors such as ILLIAC 4 or CDC Star 100 are not being thought of in a university context either in Britain or Europe, at least within the next five years.

The ENIAC, an electronic calculating machine

a, Digit trays; b, program trays; c, function unit; d, card reader; e, card punch; f, high speed multiplier; g, testing equipment.

The machine is built up in the form of a number of units each consisting of one or more vertical panels about 8 ft. high and 2 ft. wide, of which there are altogether forty. Each panel carries, at the back, racks of valves, relays, etc., and, at the front, switches, indicating lamps, plugs, sockets, etc. The different units are interconnected by two sets of lines, one set carrying signals expressing numerical information and the other set for control signals; connexions to and from these sets of lines can be plugged into the various units.

The whole machine comprises about 18,000 electronic valves, 3,000 indicating lamps, and 5,000 switches, and takes about 150 kW. in operation. Its flexibility and speed of operation will make it possible to carry out many numerical calculations, in many fields of investigation, which without its assistance would have been regarded as much too long and laborious to undertake.

Taken from D. R. Hartree's report in *Nature* (157, 527; April 20, 1946). See also *Nature*, 158, 500-506; October 12, 1946.

Introducing the 305 Series Data Terminal

The executive's portable Data Terminal

The smallest, lightest, most reliable Terminal available.

The Model 305 features:—

- * 24 lbs weight
- * 100, 110, and 300 baud speed
- * Airline hand baggage — 14" x 19" x 6"
- * Acoustic coupler suitable for U.K. and European telephones
- * All electronic, solid state technology gives reliability.

Don't shop for a computing system with your head in the clouds

If you think you need a computer, you could be making a big mistake. There are alternatives to owning an expensive machine and doing your own data processing. And the wrong decision could cost you dearly.

Take the down-to-earth approach and consider the various options. Look at computer service bureaux. Then, if good service is what you need, take a closer look at Atkins Computing.

As one of Europe's leading batch, timesharing and remote batch bureaux, Atkins Computing have an enviable reputation for quality service, individually styled to meet the varying needs of clients – from the very small to the very big. They also have a history of success in serving companies who run their own computers.

This high level of service is just a 'phone call away. Whether you need keyboard or high-speed terminals, at one location or many, in the UK or throughout Europe, Atkins Computing are there (or on their way).

So if you want an honest down-to-earth solution to your processing problems – call Atkins. It costs little to talk, and we could save you a lot.

COBOL for Students

ANDREW PARKIN

This text, based on 1974 ANS COBOL, enables the reader to become proficient in COBOL programming, preferably with some accompanying classroom tuition. It includes an extremely valuable appendix on the 1974 ANS language formats.

Paper £3.20 net

Interactive Computing with BASIC

A First Course DONALD M. MONRO

This text provides an introduction to programming in BASIC which emphasises the numerical and practical aspects of computing. The book can be used with terminals on-line to a large computer or directly with smaller self-contained machines. For those who need to move on to programming in FORTRAN learning BASIC is an ideal start.

Paper £2.40 net

Computer Interfacing and On-Line Operation

Computer Systems Engineering Series

J. C. CULEY

This book deals with the design and operation of the interfaces between small on-line computers and the processes, plant, machines, etc. which they control. It differs from others on the same subject in that it is mainly concerned with hardware.

The credibility of machine intelligence

J. R. Ullmann

Division of Computer Science, National Physical Laboratory, Teddington, Middlesex, UK

We usually use our previous experience in solving a present problem, and 'intelligence' is the name of the mechanism by which we do this. A programmed computer should not be deemed intelligent unless it is functionally similar to the brain in its use of previous experience.

WHEN Christopher Columbus sailed westwards in 1492 he hoped to reach India, and that is why the indigenous native Americans are called Indians. In 1975 there is an undercurrent of opinion that, in its established usage, the term artificial intelligence (AI) is as much a misnomer as Indian is a misnomer for the indigenous American. If AI is misnamed this is surely due to the difficulties of making a clear comparison between the problem-solving faculties of the brain and a computer.

To understand how the brain works, in the way that we know how an ordinary digital computer works, is perhaps one of the most important and urgent technical problems of the present time. The solution could provide scope for advanced automation that would very substantially alter and perhaps improve the present commercial and industrial scene. A mechanistic understanding of thought processes might to some extent benefit psychiatry. If you consult a heart specialist you can be assured that he knows fairly accurately how the heart works, but a man who consults a psychiatrist has no such assurance concerning the brain.

Science usually progresses by testing hypotheses or models. A computer that has been programmed to play chess, prove theorems, or understand natural language, may be claimed to model a thought process. To make scientific progress we should eventually compare such programs with natural thought processes (more completely than in protocol analysis¹).

Comparing computer circuitry and algorithms

In patent specifications of digital data processing apparatus the detailed physical implementation of 'and' gates and other common components is usually not specified. Instead, these components are usually specified merely as 'and' gates, 'or' gates and so on, and logical design diagrams are given which show how the various components are interconnected. For the purposes of patents, it may not matter whether the logical design of computer circuitry is implemented by transistor integrated circuits or by relay switching circuits. Thus, two computers may be deemed to be embodiments of the same invention even though, so to speak, their detailed physiology is very different.

By means of Boolean algebraic manipulation, a logical design can be changed to an equivalent logical design that looks superficially different. For instance a two-input 'and' gate can be replaced by a two-input 'or' gate that has its two inputs and its output inverted. Thus, if the logical design diagrams of two computer circuits are different, this does not necessarily mean that there is really an essential difference between them. Even if the logical designs were essentially somewhat different, this difference might be judged, for example in a legal action over a patent, to be so

slight that the two circuits should be deemed to be embodiments of the same invention.

It may be more difficult to make such judgments on algorithms that are more abstract and complicated than circuits usually are. Two algorithms are said to be structurally equivalent if, and only if, for any given set of input values the algorithms execute the same sequence of statements and follow the same sequence of branches². There are generally many essentially similar but structurally non-equivalent algorithms for computing any given function, just as there are equivalent alternative logical designs for the hardware that implements any given switching function.

Two algorithms are said to be functionally equivalent if, and only if, for any given set of input values they yield the same output values. For purposes such as proving correctness of algorithms, structural equivalence seems too tight a notion, functional equivalence seems too loose a notion, and some sort of compromise between structural and functional equivalence is required³.

Comparing brains with computers

In 1975 there is considerable knowledge of the physiology of nerve cells and the neuroanatomy of, for instance, cat, octopus, and man, but this does not provide us with a credible and generally accepted logical design for the brain or even for a part such as the visual system. We could, however, determine structural equivalence of two algorithms without using knowledge of any circuit diagram of any computer that could execute the algorithms, and absence of a circuit diagram of a brain should not therefore make us abandon hope of designing a machine that is in some useful sense equivalent to a brain.

A man may move a hand, or perform some other act, not in response to an external stimulus, but for some internal reason. A man may perceive an external stimulus but not take any physical action. Unlike many algorithms, therefore, a brain is not merely a device that determines an output corresponding to a given input, and this presents a difficulty in the determination of functional equivalence. In view of this we might confine our attention to the subset of behaviour that consists of making observable responses to stimuli, and determine whether there is functional equivalence between a brain and a model at least over this subset. There would be so many possible stimuli that we could not try them all in turn, and instead we might merely test that for a randomly chosen subset of stimuli the brain and the model made the same response.

Unfortunately this test would not establish functional equivalence, because it ignores the vital fact that a man's response to a stimulus generally does not depend on that stimulus alone, but also on his previous experience of stimuli and responses, and possibly on further rational and emotional factors. In other words, a man's output at any time may depend not only on his present input, but also on many past inputs and outputs. To be deemed functionally equivalent to a brain, a model should exhibit the same dependence of an output on many past inputs and outputs. This is particularly important if the model is intended to be intelligent, because natural intelligence is

concerned with using stored data derived from previous inputs and outputs to determine an output corresponding to a newly given input³. AI should surely model natural intelligence in this important respect, but the practical difficulties of determining this functional equivalence seem to be hopelessly great, because it is necessary to consider sets of previous stimulus-response pairs, and there are too many possible choices of the sets.

Nevertheless, it may be useful to pursue this discussion of functional equivalence a little further. A man's response to a stimulus may depend on previous experience, but not uniquely. That is to say, there are generally countless different histories of previous experience that will yield the same stimulus-response behaviour in a given situation. Conversely, a man may respond differently to the same stimulus on different occasions, without any significant change in his experience in the intervening time. In spite of the lack of a 1:1 correspondence between previous history and present stimulus-response behaviour, this behaviour generally depends on the application of intelligence to previous experience. To understand intelligence we should surely understand this dependence, and not confine our attention to present stimulus-response behaviour.

The solving of a problem, for example, proving a theorem, should for the purposes of this discussion be regarded as present stimulus-response behaviour. We usually use our previous experience in solving a present problem, and intelligence is the mechanism by which we do this. This is true even though there are usually countless different episodes of past experience that would serve us just as well. Intelligence is surely the mechanism by which we arrive at a procedure for solving a problem: intelligence is not the procedure itself. A model would be functionally equivalent to a brain only if the model used the same inputs of past experience as the brain and did not use any inputs that the brain did not use.

If a man copied from a text book a proof of a geometry theorem, we would not say in common parlance that he had used his intelligence in proving the theorem. If a man proved a theorem by executing a given theorem-proving algorithm manually, we would not say that he had used his intelligence in proving the theorem, because we would not be satisfied that he had intelligently made use of his own past experience. If a machine proves a theorem by executing an algorithm written by a man, this does not necessarily mean that the machine is intelligent, because from the vital point of view of inputs of past experience, the man and machine may not be functionally equivalent theorem provers, and indeed they may be radically and drastically different theorem provers.

Even if the functional equivalence of past experience to a brain could be determined, it would not provide a satisfactory criterion for intelligence of a machine, because a brain has other things going on in it (instinct for example) besides intelligence. Furthermore, intelligence has many different levels and different manifestations⁴. It is possible that a whole class of algorithms, not just one, should properly be called intelligent. Many somewhat different algorithms are properly classified as top-down parsing algorithms. Many somewhat different algorithms are properly classified as linear programming algorithms. To be classified as a linear programming algorithm, an algorithm need not be functionally equivalent to any given linear programming algorithm. An algorithm might be properly classified as intelligent even if it were not functionally equivalent to any given intelligent algorithm or to any brain.

Exact functional equivalence seems too strong a criterion, so we must fall back on a looser notion of functional similarity. It would surely be wrong to say that a model was intelligent unless it was functionally similar to

an intelligent brain in its use of previous experience in problem solving.

Not comparing brains with computers

McCarthy says that the main scientific activity of AI researchers is, or should be, "studying the structure of information and the structure of problem solving processes independently of its realisation in animals or humans"⁵. McCarthy's statement broadly defines an area within the field of computer science, and if only some name other than artificial intelligence had been assigned to this area, there would be less confusion and misunderstanding. Just as one is not free to define an artificial diamond to be a lump of coal, so also one is not free to assign the name 'artificial intelligence' to a field of study that may only be obscurely related to intelligence. All such relationships are likely to remain obscure until intelligence is precisely, scientifically, and acceptably defined.

But by clarifying judiciously chosen computational problems, and by discovering and comparing different methods by which these problems can be solved, we may perhaps eventually begin to agree that some problem solving processes are more intelligent than others. It is possible that two solutions to a given problem may be equally successful from a pragmatic point of view, but one solution may be judged more intelligent than the other in view of the type of past-experience data that it uses.

The use of computers in weather forecasting and in the computation of rocket trajectories involves machine representation of knowledge but does not belong to the AI field, presumably because the computations are numerical. AI^{6,7} is concerned primarily with those non-numerical problems, such as chess, theorem proving, and robot control, at which men excel over computers. In solving such problems there are two schools of thought in AI, the generalist and the specialist⁸. The specialist school is prepared to make more use of *ad hoc* programming than the generalist school.

To make a computer exhibit limited understanding of natural language^{9,10} it is convenient for the programmer to use his knowledge of the world, that is, his semantic knowledge, in writing procedures, and this practice is called procedural embedding of knowledge. This practice is characteristic of the specialist school⁸. When new knowledge is to be used, new *ad hoc* instructions must be written, and considerable reprogramming may be required when a procedural embedding system is extended to cope with a somewhat new problem domain¹¹.

The Stanford Research Institute problem solver is used to control a mobile robot in tasks such as finding a box and pushing it through a doorway into another room¹². The core of the robot control system is an automatic theorem-prover that determines plans of action by proving theorems in predicate calculus. Knowledge of the world is expressed in statements in the predicate calculus, or, in other words, knowledge is assertationally embedded in the system. Assertional embedding has the advantage that the problem-solving system can be extended to new problem-solving domains without extensive reprogramming, since the principal changes can be made merely by changing predicate calculus statements. The theorem prover is a general purpose program that is independent of specific problem semantics, and this¹¹ provides us with a very clear example of generalist work. It is less clear how much generality there is in the interface between the real physical world and the assertional representation of it. In a generalist system the requirement for generality precludes the limitless sophistication that can be built into a specialist system *ad hoc* programming; and the problem of keeping abreast of changes in the world may be particularly acute in a generalist system¹².

Acquisition of knowledge

Whether knowledge is represented procedurally or assertionally, it must first somehow be acquired. Feldman and Yakimovsky¹³ have devised a system that automatically labels area of a photograph as "sky", "mountain", "grass", and so on. Indeed the system partitions a photograph into such areas. This system uses previous knowledge that in the world "sky" is above "mountain". Here, "above" is a relationship, and in partitioning a photograph the system exploits knowledge of many such relationships: Feldman and Yakimovsky have developed a general technique for using such relationships, provided that these are given to the system. The system has statistical learning capabilities but has no means of automatically acquiring knowledge of these relationships, for instance by processing unpartitioned specimen photographs of many different scenes.

This acquisition problem does not seem to be intractable, and indeed I have already investigated a related problem¹⁴, the first of a series in AI¹⁵. Although this work was admittedly abstract, primitive, and impractical, it did show that one can make headway with the segmentation of a pattern into parts, given as data only a set of unsegmented specimen patterns composed of different combinations of parts. A solution to this problem would seem, to my intuition, to be nearer to intelligence than would a segmentation technique that relied on a human to supply knowledge of relationships between parts. This also serves to illustrate my previous remarks about previous-experience input data.

For practical purposes of segmenting a photograph into semantically homogeneous areas (for example in aerial photointerpretation) there may be no advantage in automatic acquisition of relational knowledge that is used for achieving segmentation. Instead, this problem of acquisition may be left to those of us who do not forget that there is only limited information capacity in the genetic code by which the brain structure of an offspring is determined by a parent, and to those of us who would prefer to model the lower levels of practical intelligence⁴ before proceeding to the understanding of natural language by the machine^{8,16}.

Intelligence

In a top-down parsing algorithm, or any other kind of algorithm for that matter, there is no single instruction that is the "heart" of the algorithm. A top-down parsing algorithm is recognisable as such by its overall structure, in spite of the fact that it contains no tangible heart. A written word is recognisable as a combination of letters, despite the fact that it contains no letter that other words

do not contain. An algorithm that should properly be called intelligent may be recognisable by its overall structure, and "we should not let our inability to discern a locus of intelligence lead us to conclude that programmed computers therefore cannot think"¹⁷, but this does not imply that all problem solving algorithms should properly be called intelligent. The presence or absence of a heart, locus, or "blinding white light" is irrelevant to the determination of intelligence of an algorithm.

To Minsky "... 'intelligence' seems to denote little more than the complex of performances which we happen to respect but do not understand"¹⁷. To me "intelligence" denotes a very distinctive class of problem-solving processes, and I do not think that the word "intelligence" should be applied to radically different classes of problem-solving processes, even when these successfully solve the same problems.

Finally I shall hazard some guesses about the distinctive nature of intelligence. It seems safe to guess that, in the brain, intelligence is realised by a highly parallel computation using distributed logic. This computation could presumably be simulated on an ordinary digital computer, but perhaps awkwardly, inelegantly, and even impractically. Animals and people do not always seem to need the same sort of instructions that computers need, and I guess that in some cases intelligence is realised in the brain by a sequential process that does not use stored instructions: the process is non-programmed, not self-programmed, in that there is no stored program. I guess that in the design of the brain there are solutions to two of the salient problems of computer science: the mitigation of programming effort, and the organisation of parallel computation.

Distributed computer networks

Peter T. Kirstein

Department of Statistics and Computer Science, University College, 44 Gordon Square, London WC1H 0PD, UK

How desirable and inevitable are large heterogeneous, distributed computer networks? In this article Professor Kirstein, whose group at University College London operates one node of the large international ARPA network, describes the motivation for setting up such networks and the problems which must be resolved before they are deployed more widely. Those problems are often more political and sociological than technical.

THERE is considerable argument as to what is meant by a computer network. Any large modern computer system contains several processors and for commercial or technical reasons these may be mounted in one set of cabinets. Nonetheless, they could still be regarded as a network, and here I shall define a computer network as a collection of computers, connected through communication lines to other computers or terminals. This definition will not please all the proponents of computer networks: some will consider it too narrow, because it does not include single collections of connected

processors; others will consider it too wide because it includes Star systems (Fig. 1). There is, however, a qualitative difference between the purpose, technology and potential of the systems which come under my definition of a computer network and single collections of connected processors.

Figure 1 shows the principle ingredients of a Star-organised computer network. A single computer centre (C) is connected through a data network (N) to a number of terminals (T). Each of the elements C, N, and T can have different levels of sophistication. The computer centre can be one processor or a set of computers at one site (perhaps interconnected, as shown in Fig. 1). The data network can be just the public switched telephone network (PSTN), the British Post Office experimental packet switched service (EPSS), a distribution system based on leased lines and privately owned switching computers, a set of leased multiplexed, telephone channels, or a mixture of elements like these. As an example, Fig. 1 shows a hierarchical leased network of central concentrators (CC), and remote concentrators (RC) connected to the PSTN. The terminals may be either simple keyboard terminals (or displays), or more complex computer work stations which control card readers, printers, magnetic disks and tapes as well as keyboard terminals. A key aspect of all these computer networks is the desire to increase the catchment area of the individual computer sites, and to make the computers available to people elsewhere.

In a very simple system, the C of Fig. 1 may be only a single computer, the N, the PSTN, and the T keyboard terminals; many T of the smaller time sharing bureaux are so configured. A single computer (H in Fig. 1) is not, however, sufficiently reliable; for better availability, multiple computers are incorporated in the computer centre. The PSTN is adequate for local access to keyboard terminals. To provide a larger catchment area at cheaper cost, however, the installation of concentrators (RC in Fig. 1) connected by leased lines to the computer site is more cost effective. The PSTN is restricted, in the UK, to 300 bits per second (b.p.s.), which is 30 characters per second in two directions simultaneously, or somewhat higher speeds asymmetrically (for example, 100–200 characters per second one way, 7 characters per second the other). Thus, to provide higher speeds (for example, for batch card reader–line printer terminals) leased line networks are requested. These lines can go direct to the central site, C, or to nearer concentrators (RC in Fig. 1).

Because the computer systems themselves were the least reliable components, it was unnecessary with the earlier networks based on single computers in central sites to put much sophistication in the data network. Such systems are still limited, however, to serving about 100 users simultaneously. To improve availability, multiple mainframes were incorporated in C. Moreover, performance was improved by introducing a certain amount of functional specialisation. For example, in both the London¹ and Manchester University regional computing centres, one machine is being used for the main large batch processing, and other front-end computers (FE) deal with the interactive traffic and submit work to the batch processor.

No commercial limit has been reached yet on the number of terminals that can be serviced simultaneously by a system with the topology of Fig. 1. Indeed, some of the larger time sharing bureaux have used it to service several thousand terminals simultaneously. Of course, in those circumstances the organisation of C is complex, with duplicate access to the communication lines, processors and files. These precautions guarantee the continued availability of resources in the event of failure of most individual subsystems.

The data networks are configured very carefully, with due consideration given to the connections of RCs to CCs, duplicate CCs, the optimum siting of RCs, and so on. Such systems must provide highly reliable access at least for interactive activities. The General Electric Network² and TYMNET³ are the best developed of this class.

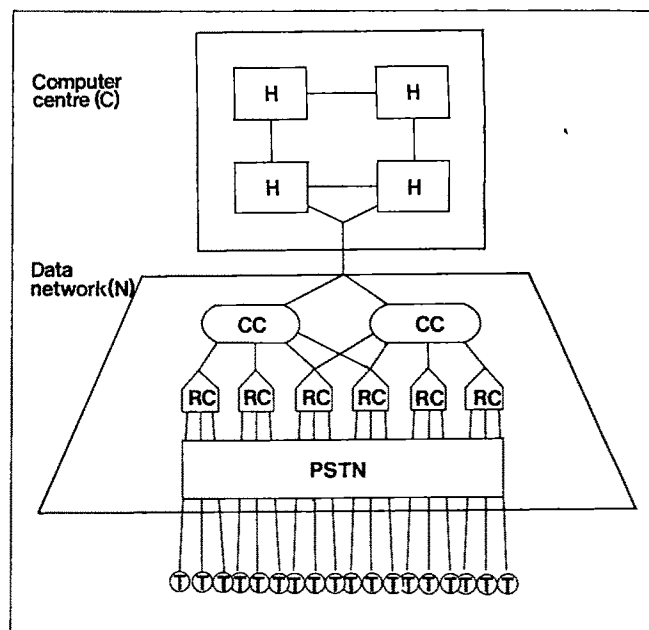

Fig. 1 Star-organised computer network. H, Hosts; CC, central concentrators; RC, remote concentrators; PSTN, public switched telephone network; T, terminals.

The availability of different processors in C (Fig. 1) allows a considerable degree of functional specialisation. One or more systems may be used only for interactive editing, others for access to specialised data banks, and yet others for very large parallel processes. One noteworthy example of this functional specialisation is the ILLIAC IV complex at NASA-AMES⁴. At last count it contained more than 30 computers, from those driving the 10^{12} bit store, controlling the communication functions, to those providing interactive file manipulation and controlling the 64 parallel arrays or processors.

There is one facility not provided in the systems of Fig. 1: geographical separation of the host (that is, the main service machine). For many reasons this distribution can be very important, geographically distributed sites may have a large local catchment area, so that only a small proportion of computing need, or should, be exported. A balance between gains from larger computing centres against added communication costs can make the topology of Fig. 2 most attractive. In practice, computing centres are often brought into being for local reasons, but cannot supply all local needs. In such conditions the topology of Fig. 2 is a natural outgrowth. Here, the individual host sites, C, may have the form of Fig. 1 in its simple or more complex embodiments, each site responsible for a distribution network, N, to its own customers, T. In addition, there is now a high level data network (HLDN) connecting the host sites. The terminals can be switched through the HLDN to other sites. Three networks which use this technique are the early versions of ARPANET⁵, the French Cyclades⁶ and the UK South-west Universities Network (ICNS)⁷. As a final level of sophistication, the terminals (T, in Fig. 2) can also be introduced directly to the HLDN, as on the present versions of ARPANET⁵ and TYMNET³. Obviously, practical networks do not always allow a neat classification into those of Fig. 1 or Fig. 2. For example, the General Electric network² is essentially of the type of Fig. 1, with a high level data network connecting individual computers in the computer site. The computers themselves are distributed in two centres, and could be spread over more than one network with no change of technology.

Using the networks shown in Fig. 2 it is possible to have a more rational growth policy. One centre can be expanded and some of its surplus used to delay the need of expansion at other sites. Centres not willing to forego their own computer systems may be much more willing to supply a highly specia-

Fig. 2 Distributed computer network. HLDN, High level data network; other symbols as in Fig. 1.

lised proportion of the computing requirements for a whole community. The difficulties posed are not technical but political and sociological.

The national communication carriers would like to offer the maximum portion of data network traffic; at the least, they will always lease transmission channels. Many are proposing special data networks which also provide any switching and multiplexing required. Examples of planned offerings in this area are the US TELENET⁸, the UK EPSS⁹, the French TRANSPAC¹⁰, the German EDS¹¹, and the Nordic network¹². The communications carriers would like to separate out the data network portion as much as possible from the rest of the network, and some of the commercial interests (for example, TELENET and TYMSHARE) would like to provide them as commercial services.

With the systems of Fig. 2, very careful definition is required for the communication protocols at different levels. When the different computer systems are from the same manufacturers, as, for example, in the South-west Universities' network, the problems are easier. But when the systems are different, as in ARPANET⁶ and Cyclades⁶, very careful design and implementation is required¹³. Sometimes, as in the UK EPSS, the carrier defines one portion of these protocols, but in such

cases it may still be necessary for those responsible for connecting in computer sites or terminals to define other levels¹⁴.

The data communication network may be very heterogeneous itself. Besides containing a very hierarchical structure, it will in the future include new technologies. In the US ARPA has been used to investigate the use of satellites for broadcasts¹⁵.

A set of experiments to investigate this technique, to be carried out jointly by ARPA, the British Post Office and a number of research organisations (including my group at University College, London (UCL)) started in the summer of 1975. ARPA has also been used to investigate access to the local nodes by packet radio¹⁸.

The ARPA computer network and UK usage

In the ARPA network, the sites are connected together by a communication subnetwork (ARPANET), 50×10^3 b.p.s. (Fig. 3). This comprises leased lines (usually at 50×10^3 b.p.s.) connecting communications computers called Interface Message Processors (IMP)¹⁷. The system has extra connections to permit alternate routing in case one node becomes inoperative. The host computers (H) are connected to the IMPs, and may be local or remote; in the latter case the connection between the IMP and the host is by a leased telephone line. In some cases only host computers are attached to the IMP; in others, terminals can also be attached. The latter set of communication computers are called terminal interface message processors (TIPs)¹⁸.

The important attribute of this network is that messages between hosts are split up into packets. Each packet is up to 1,000 bits long and contains the full information about its source and destination in its header. The IMPs contain the information on how to route from the source to the destination. Cost saving arises from the possibility of using a much smaller number of communication lines than would be required in a system in which each pair of nodes was joined by a pair of lines. The fact that the destination information is contained in the header saves the time and overheads required in setting up a virtual circuit. It is possible to use high-bandwidth lines with appropriate cost savings, and achieve a maximum transmit time between sites, in the absence of satellite hops, of 200 ms for single packets of 1,000 bits. ARPANET now stretches to Hawaii, Norway and London (Figs 3 and 4).

The connection of those sites sited near the IMPs to ARPANET relies on a special hardware interface because of the lack of standard communication interfaces. This policy has also been used in later developments of ARPANET and similar sub-networks^{5,8}. A considerable body of software is required in the hosts if this heterogeneous collection of computers is to be used in a somewhat homogeneous manner. There is a network control program, which embodies the procedures agreed for a process in one host to connect to a process in another. There

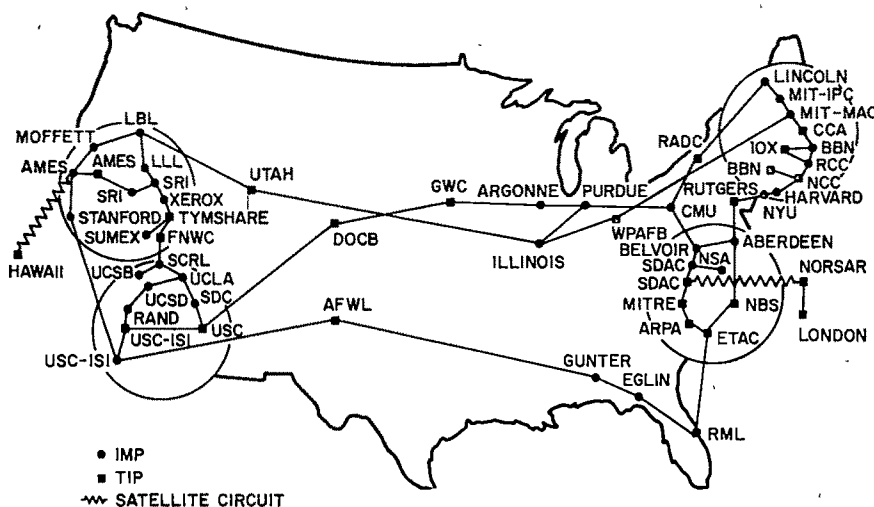

Fig. 3 Geographical map of the ARPA network (April 1975).

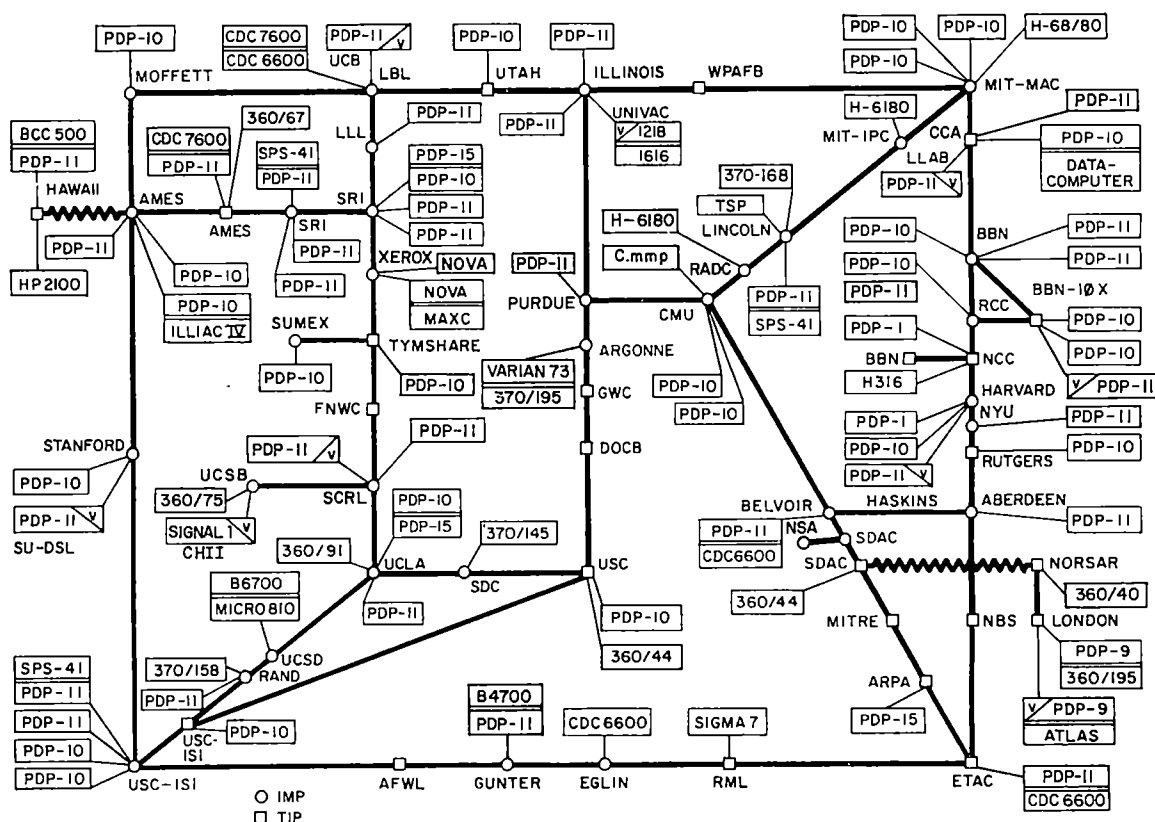

Fig. 4 Logical map of the ARPA network (April 1975).

are protocols for network virtual terminals and file transfer. Even higher functions such as Graphics and Mail Transfer have been standardised¹³. In this context the word 'protocol' means an agreement by the participating sites to implement programs which will accept the standard format of data and control for the relevant functions.

The ARPA network has not gone as far as possible in standardisation. Though there have been discussions of network-wide job control or command languages, and even editors, these have not been implemented in practice. This was partly because of the lack of effort available, and partly because of the increasing difficulty in agreeing on standards for the higher functions. In our experience about 8,000 words of code (in our system 4,000 words resident) are required to implement these protocols.

To operate such a network it is essential to have a network control centre¹⁹. Extensive information on how to use the systems must be made available. Much of this is kept on-line on the host computers; however, a special facility, the Network Information Centre, has been set up for this purpose. Lack of funding has not allowed this to be kept up properly leading to some problems. In the UK, my group is providing a documentation and advisory service to other UK groups using the network. For this purpose we have arranged to make many documents available in a special collection in the British Library (Lending Division).

It is very difficult to organise efficient advisory and co-ordination activities in such a network without good, simple message services. For the research most of the hosts have instituted some facilities for exchanging text messages between the users. The procedures have been standardised, so that the messages can be sent to other sites. Simple composition and retrieval facilities have also been provided (for example, simple editing, ability to append lists of addresses, single line titles, procedures for listing only the titles of messages, and so on). In addition, there are facilities for linking terminals together to enable two or more terminals to communicate in

real time with each other—even though they are attached to different hosts. This is very interesting and complex²⁰, though its uncontrolled use would be against the regulations of the PTTs. In the context of the international ARPA network its use is only permitted for specific purposes concerned with the computations in progress. An important lesson to be learned from the ARPA network is that the communication sub-network, ARPANET, which is the entity which will in future be provided more by the PTTs (refs 8–12), is only one part of the infrastructure required to make such networks function effectively. The subnet, because it is usually implemented by one organisation, should proceed smoothly. The development of the rest of the infrastructure can be much more time consuming.

In the context of scientific multi-user networks the types of use which are being made of the hosts will be of interest. The ARPA network is being used operationally for a large number of projects. It is the principal means of entering jobs into the Illiac IV computer; a substantial proportion of the use of MULTICS, the UCLA IBM 360/91, and many of the TENEX sites work through this network. Among the substantial applications of ARPANET are the acquisition and analysis of seismic data, large scale climatic modelling, the administration of ARPA projects, and the coordination and cooperation of hundreds of research programs. A partial list of projects which used the UCL link of the ARPA network during 1974 is given in Table 1. This list encompasses a broad range of subject areas, research institutions, and government departments; the uses are discussed much more fully elsewhere²¹. Most, however, involve cooperative activities, between different research groups in the UK and USA. Sometimes the cooperation involves shared use and development of the same programs (for example, University College and the Royal College of Arts, Table 1); sometimes the computer resources of one group are traded for those of another; sometimes one group has access to a computer system belonging to another so they can develop software of mutual interest

(for example, Utah's use of the RL 360/195). Sometimes the incentive to cooperation is access to data bases built up jointly or just accessed by more than one group (for example, the Blacknest Seismic Data Base and the British Library use of Medline)²², sometimes the main motivation is just to have the groups share their research experiences more promptly and completely (St Bartholomew's Hospital and Southampton University's use of the teleconferencing system Forum)²³. Of great importance here is the unpredictability of the uses. In 1971, when the UCL project was proposed officially, there were eight proposed users (all in computer science); of these only half ended up using the link in practice. All the others in Table 1 starting applying (and are still applying at the rate of about two a month) once the link was established.

Motivation for computer networks and their development

There are six fundamental reasons for preferring the use of a network to that of a local machine.

First, the cost of running a particular job may be substantially lower on a larger machine than on a smaller machine, even allowing for communication costs. For that reason, a larger computer than is required for local computing, with a suitable data network to enlarge the catchment area, may be economically attractive. That is the rationale behind the establishment of the University Regional Computer Centres by the UK Computer Board. Wells²⁴ has commented that the cost of processing goes down as the square of the computer power, whereas the cost of file storage varies linearly for any particular machine type.

Second, with a large collection of computers in a network and corresponding catchment area, it is possible to make smoother increases of capacity to meet demand, and to provide better reliability and availability. This is one of the rationales behind the TYMNET and General Electric networks.

Third, with a large catchment area, covering many time zones, the diurnal demand cycle means that the peak computing requirements of some of the users will come at the low activity periods of others. The effect is very pronounced in

the networks which span North America, Europe, and the Far East. Even with Europe and North America covered alone, the effective peak day is 18 h long.

Fourth, specialised resources like data bases, programs, or special hardware, which would otherwise not be available, can be accessed. This is the major motivation of many of the users of service bureaux and stock exchange dealings also come into this category. In the scientific field seismic and weather data bases, bibliographic data bases, large data bases developed for high energy physics experiments and molecular structure come into this category.

Fifth, for research or other groups to cooperate on the same or related projects they may need access to each other's data or programs. They may also need to share messages with short response times, or even in real time, with several other people at different sites.

Finally, there may be a requirement of computing capacity at each site; the network environment enables one site to increase capacity beyond the local requirement and export some capacity to others in the network. This leapfrogging technique enables all the sites to vary their systems progressively with minimum dislocation and short term over-capacity. It enables different centres to specialise on specific areas, while keeping all areas available to local users. The South-West Universities Network works like this.

For some applications the type of network used is immaterial, but traffic considerations and the cost of communications make those like the ARPA network the most economic. This is particularly the case when there is a genuine need for local computing—often resulting partly from the difficulty in attracting good staff without a local computer.

A closer look at the costs of the different applications of computers, shows that there are often considerable advantages in dedicating computer systems for specific applications or types of service. One reason for this is the pure hardware and software cost of providing the computation for each item. Another is to avoid the cost of duplication at development and storage stages of the packages, and to provide the relevant advisory facilities.

Table 1 Partial list of UK project using the ARPA computer network through the UCL node (March–December 1974)

UK organisation	US partner	Purpose
Blacknest Research Establishment	Lincoln Laboratory, MIT; NORSAR, Norway	Cooperative construction and analysis of seismic data bases
British Library (Research Division) with 15 UK centres under their sponsorship for a specific experiment	National Library of Medicine	Experimental comparison of MEDLINE, a medical bibliographic information retrieval system, with a similar UK system
Cambridge University	Utah University	Development and comparison of algebraic manipulation system
Culham Laboratory	NASA-AMES	Application of ILLIAC IV to magneto-hydrodynamic computations using symbolic manipulation techniques
Royal College of Art	Harvard, MIT	Development and evaluation of space-planning systems in architectural design
Rutherford Laboratory (including its user groups at Oxford and Surrey Universities)	Illinois University Maryland University Harvard University Chicago University	Exchange of software and data for theoretical high energy physics calculations
St Bartholomew's Hospital Medical School	Brookhaven National Laboratories	Teleconference on human response to sulphur pollution
Southampton University Politics Department	University of California, Santa Barbara	Teleconference on political simulation models
University College London, Department of Statistics and Computer Science	Stanford University Bolt, Beranek and Newman	Experiment on the requirements for interconnection of computer networks

A rational policy of computer provision for, for example, the university and research communities would therefore include some local, general purpose, computing facilities (probably not connected to a national network), some regional, large scale, general purpose computing facilities (part of a regional network), and some specialised facilities (clearly, part of a national, and in some cases an international, network). Some types of computation may be done best in commercial bureaux, and even that should be permissible. Together with the build up of computer facilities in this way, some control is essential to ensure that the computing is done on an appropriate facility—and that the operators of facilities do not duplicate unduly activities already carried out well elsewhere. Such a computer policy raises many problems: on the one hand it is ludicrous to develop a complete expensive body of programs and data bases in a specific area as a general service, if another adequate set exists already accessible by the same user community; on the other, one should not prevent progress in providing new and better facilities. Sometimes, such improvements can be made in an evolutionary fashion but at others a completely new system is required.

Using any network on a large scale requires resolution of 'balance of payment' issues. It seems a fact of life at the moment that institutions want the maximum facilities locally, and resist resources going elsewhere. They prefer to be net exporters—and to be paid to export. For the concept of specialised resources to work, means must be found for financing their development and utilisation—even at the cost of local generalised facilities. Resolution of this problem becomes progressively more difficult as the computers become wider apart.

In the UK, the Science Research Council has succeeded in this respect with the High Energy Physics Community. Regional University computing centres have been installed for large scale general computers. Only now is there discussion of a 'computer aided design' centre for the universities (though there is one in Cambridge run by the Department of Industry). This concept should be carried much further—but needs a widespread data network to permit its implementation. A candidate for this network should be in existence soon in the UK with the development of the Post Office's Experimental Packet Switched Service⁹. Technically, international usage is possible, and there are communities who desire and require such use; it must be resolved, however, whether the appropriate payments or regulation mechanisms can be devised.

There is a further serious question to be resolved on network usage, and that is a complex mixture of regulatory and economic issues. No tariffs for EPSS have been published. It

is clearly cheaper to set up private user data networks (like those of Figs 1 and 2) than to use only the facilities provided by the Post Office—though this is not necessarily so in the US where 'value added networks' are permitted²⁰. In the UK, and even more internationally, there are severe restrictions on which users may join together in a private network. There are, for example, several very large bibliographic data bases owned and operated by different organisations²². These fall clearly into the description of the 'specialised resources' mentioned already. In the UK (and in many other countries) a private data network operated by one organisation is not permitted to provide the public access to several such systems.

This problem is even more difficult if the common user service is to be provided internationally. We can expect a continued dialogue between the PTTs and the service suppliers and user communities to modify tariff and regulatory policies in the light of economic pressures and technical advances.

Technology now exists for large scale, distributed, heterogeneous computer networks. The most common method of implementing them is by a separate data network with host computers attached. There is still some discussion as to what should provide the data networks, what facilities they should contain, and how they should be tariffed. The main bar to a wider deployment of such networks is the need to resolve the organisational, regulatory and financial issues they raise.

Computers and the printing industry

Michael Barnard

Macmillan Journals Ltd, 4 Little Essex St, London WC2R 3LF, UK

As page composition from digitised information replaces the manual assembly of type, the printing industry struggles to absorb a technology in which the compositor becomes a computer operator and the production controller a systems analyst.

CRITICS of print technology are fond of pointing out that if Caxton returned to the industry today he could walk back into his old job with the help of a fortnight's refresher course at the London College of Printing. Certainly it is true that

Gutenberg, who developed moveable type in the fifteenth century, would have no great difficulty today in locating a composing room which used materials and crafts recognisable to him, whether in his native Strasbourg, in Britain or the USA.

For many years it seemed strange to technicians outside the print industry that something like an office typewriter could not be put on-line to a computer and thence to the printing process. In 1867 a Milwaukee editor, Christopher L. Sholes, patented the machine which gunmakers E. Remington and Sons manufactured as the Remington Model 1, yet a century later even the simplistic use of an IBM typewriter driven by punched tape or on-line to a small digital computer is an innovation in some print houses.

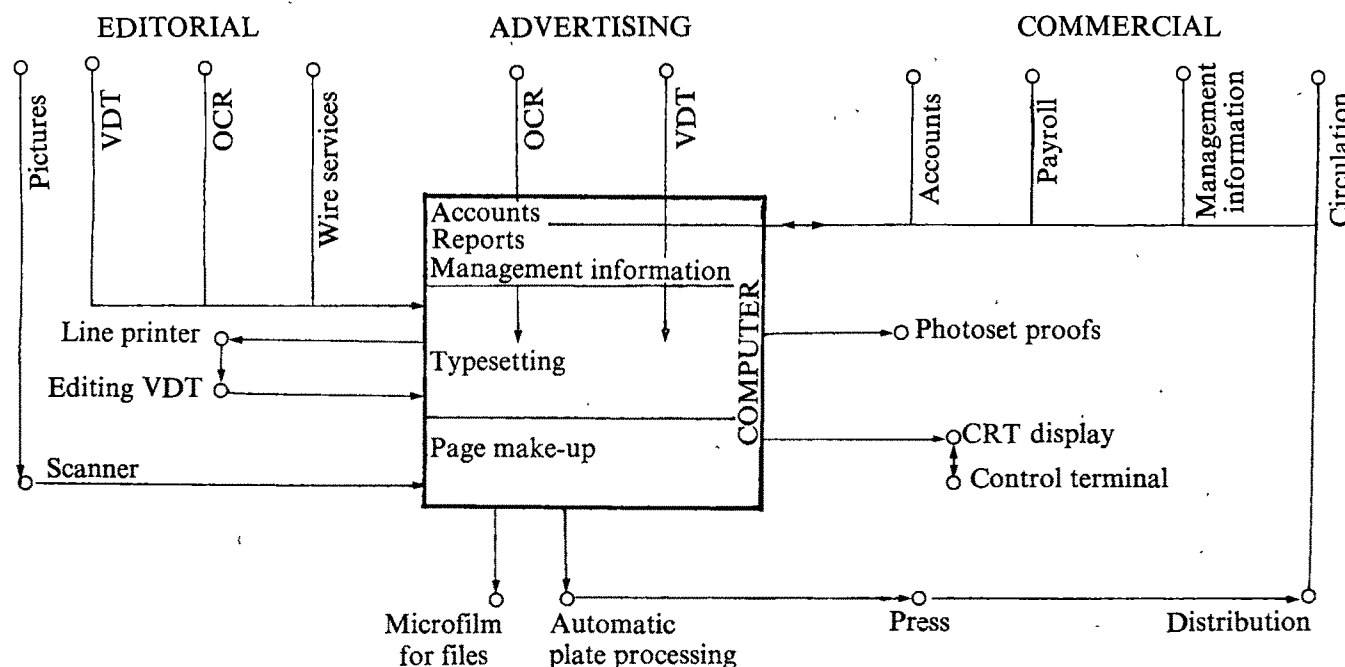

Fig. 1 A theoretical typesetting and page make-up system for a daily newspaper. Picture input is the present obstacle.

Countless frustrated authors and publishers have condemned the mediaeval technology of typesetting while at the same time feeling some affection for the traditional techniques which for centuries defied any degree of mechanisation. It is therefore in some ways sad but probably inevitable that the computer in print is ultimately destined not to refine the traditional craft skills but rather to replace them.

If printing is considered a two-part operation comprising first, the processing of words into a printable form and, second, the manufacture of a readable product (which is possibly in the long term an unnecessary breakdown), then the first part at least can be achieved at present by computer-driven hardware controlled by technicians who are not necessarily trained printers.

The feasibility of the jump—after 500 years of technological stagnation—from techniques which involve the individual collation by hand of lead letters or lines to systems which effectively dispense with manual skills altogether can only be appreciated in the context of the second part of the production process, the printing operation, since this largely governs the form of origination necessary.

Caxton and Gutenberg, on their reincarnation as twentieth century printers, would print by the letterpress process, involving the pressure of an inked relief image against the paper. In this case, the opportunity for the use of a computer to progress beyond mathematical problems of letter assembly (such as word and letter spacing) is qualified by the unavoidable complexity and size of the machine which would then be necessary to assemble automatically a page of relief metal. Consequently only limited mechanical assistance of any sort has proved to be economic in metal typesetting. It is possible and usual, of course, to cast type in 'hot metal' by machine, but normally this process ends with the collation of lines of type, after which pages have to be made up skilfully by hand.

The Monotype, which automatically casts individual letters in lead on instructions from a keyboard perforated paper roll was invented by Tolbert Lanston in 1887; Mergenthaler's Linotype, which casts lines of lead type in a semi-automatic process from directly keyboarded commands, went into production a year earlier and became the standard newspaper setting machine. Still in general use as updated models throughout the world, both machines retain the appearance of having been created by Heath Robinson after a heavy night out.

The Linotype and Monotype represent the most commonly used methods of mechanically casting metal type but manual expertise is needed both in operating complex keyboards and in making up pages from the set type; multiple installations are necessary if any volume of setting is to be achieved.

Computers are successfully used to produce perforated tape to drive linecasting machines, but the metal output is too restricted to allow much application beyond the production of lines of justified type.

Although letterpress has inhibited computer potential, the commercial development of offset lithography has encouraged it. The offset lithographic printing process was discovered accidentally in 1796 by Alois Senefelder who was working on a method for reproducing music notation, but it was not until well into the twentieth century that extensive commercial use was made of the process. Lithography uses a planographic plate which is developed photographically, so anything which can be photographed—even typewriting, for example—can be converted into a printing plate.

The lithographic technique involves the use of pre-sensitised plates exposed through a film (negative or positive) of the page of type and illustrations. Development of the exposed plate leaves the non-printing areas hydrophilic with the printing surfaces ink-attractive. Judicious application of water, then ink, to the cylindrically mounted plate allows the transfer of the exposed, inked area to a revolving rubber blanket and thence to the paper.

Replacing metal

As offset lithography slowly replaced some letterpress installations, the inconvenience of metal type became increasingly burdensome. Since input to the lithographic plate-making process was in the form of 'flat artwork' ready to photograph, metal type needed proofing on high quality paper before it was ready for the camera.

Alternatively, other methods of composing type could now be used, and as paper or film—as opposed to metal—output was required from the composition process, electronically controlled typesetting machines became convenient and economic.

Two main systems have been used extensively: a 'near print' process which uses a typewriter-based device such as the Friden Justewriter or IBM Selectric to 'type' setting as a straight

manual operation or from coded tape, and a photographic process in which the typesetting is produced as film or a bromide print. Both methods can use binary logic to solve the arithmetical problems involved in setting letters of varying widths, but for various reasons, including speed, versatility and the suitability of the end product, photo- and filmsetting have made the widest use of the computer. It is therefore relevant to look briefly at the mechanics of photosetting.

The early filmsetters (for example the first Monophoto) were mechanically based on hot metal casters with matrix cases of typographical characters on film replacing the caster's case of 'moulds'. A quartz-iodine light source projected a selected character on command on to photographic film. Most electronic photosetters, on the other hand, store characters on disks, drums or grids. Disk or drum stores rotate continuously and characters are illuminated by xenon flash tubes. Grid characters are exposed in a stationary position. The sizes of characters may be controlled optically by moving or changing lenses within the exposure routine or by storing character negatives in varying sizes.

Such photosetters may be quite sophisticated in themselves, with special-purpose minicomputers controlling the word and letter spacing, or they may be 'slave' units operating on instructions from a separate computer. Input is usually by Qwerty keyboard, either direct entry or off-line, using punched tape. If a small photosetter is using its own minicomputer, keyboards will normally be off-line, since its output speed will permit the consecutive acceptance of tapes from several keyboards while its computer will not have the power to store or process several inputs concurrently.

The fastest photosetters, mainly evolved in the past three years, use a cathode ray tube (CRT) to recall digitised characters which can be kept on file in a backing store. CRT photosetters are very fast and under intensive development, and are rapidly becoming economically viable for medium-sized printers.

Justification routine

The extent to which computer power is used in typesetting depends on economics, speed, volume of work, complexity of material processed and the number of ancillary operations involved.

Justification was the first and most obvious task to set a computer. By tradition, most printed matter, unlike typewriting, has proportionately spaced characters (that is, letters of varying width) and a straight (or 'justified') right-hand margin. The justification is achieved by varying the spaces between words within set minima and maxima. These parameters are stored in the computer memory together with data on character widths and line lengths ('measure'). Justification can then be achieved rapidly by subtracting from the measure the width of each

Table 2 Capital costs of a hot metal composing system, a conventional photosetting system and a practical ideal system

Hot metal £	Photosetting £	Practical ideal £
292,269	240,400	448,120

character as it is read, running back to the last space when the line overflows, and distributing through the inter-word spaces the total value of the space removed from the line end.

If the criteria for inter-word spacing do not allow this 'infilling' in a given case, then hyphenation is necessary. Computer hyphenation has been the *bête noire* of many photocomposing systems. The problem is that although it is possible to hyphenate by logic, there are, as in most grammatical rules, exceptions, and they are really too numerous to ignore. There was a short-lived move by some newspaper proprietors using photosetting to impose irregular hyphenation on their readers, but they discovered that the irritant factor was too great. Some systems enable the operator to decide hyphenation by displaying the word, but obviously delays of this nature are not ideal and the present practice is for computers to store an 'exception' dictionary, the routine being to search the dictionary for the word and use the recorded hyphenation break if it is there, or otherwise to hyphenate by logic.

With short-measure work such as newspaper setting, 50% of the total setting time¹ can be spent justifying by traditional methods, so keyboarding in an unjustified mode and leaving spacing and hyphenation activity to the computer has obvious attractions in terms of speed. The resulting possibility of boredom for the keyboard operator can, however, be a problem.

Once the attractions of computer justification were established, larger machines began to tackle fairly obvious tasks which needed more memory, considerable random access or more sophisticated programs: 'formatting' by the use of limited command key strokes to produce commonly used typographical combinations; tabular composition; scientific setting using a wide variety of characters; mathematical composition with superior and inferior characters, special symbols and variations from the base line of the type; the acceptance and re-formatting of wire service material, and so on.

Optical character recognition

Methods of input were scrutinised as the new technology threw into focus the inefficiency of 'double keyboarding'—once by the author or his typist and then by the typesetter. Optical character recognition (OCR) is one solution with which the newspaper industry in the USA, Britain and Europe is being wooed. Like most flirtations, this is running a bumpy course, but the principle is sound enough.

Typewritten manuscript is scanned by a 'reader' using photocells and the character which is recorded digitally is compared with master images held in binary form in the memory. Imperfectly formed characters will not be recognised on comparison with the memory data so fairly strict control of typescript quality is necessary. Specified typefaces must be used and carbon ribbons are used so that an even impression is made. Character recognition may still be thwarted by dirty typing heads, marks on the paper and so on, in which case the machine displays the offending line on a CRT with a query device such as a tick over the unrecognisable character.

Post-recognition logic may be very sophisticated with the acceptance of extraneous characters or character-combination codes for instructions such as 'delete previous word' or 'delete previous line'—given detailed code command programs and wide line spacing to allow for insertions, extensively edited copy can be accepted. Notes can be made on manuscripts with 'non-reading' pens, so most combinations of writing—editing—revising are possible. Output is normally to punched tape which can then be forwarded to the filmsetting computer.

Table 1 Running costs of a hot metal composing system, a conventional photosetting system and the practical ideal system

a Present running costs per year			
	Hot metal £	Photosetting £	Practical ideal £
Depreciation	15,048	29,580	68,040
Labour	209,962	183,130	85,179
Other costs	21,400	19,285	18,060
	246,410	231,995	171,279
b Forecast changes* in running cost indices due to rising labour costs			
	Hot metal	Photosetting	Practical ideal
Present	144	135	100
Two years	156	146	105
Five years	178	165	114

*Taking present 'Practical ideal' as 100 and assuming labour costs will rise 5% more per year than Depreciation and Other costs shown above, the changes in relative indices at two years and at five years due simply to this extra 5% in labour costs would be as shown.

Typewriter keyboards do not comprise a wide range of characters so the type of text which can be processed is restricted. Classified advertisement typesetting has been handled efficiently by OCR with the 'tele ad' girl who takes the advertisements by telephone producing the typescript which will become the typeset advertisement.

Extension of the use of OCR to general purpose setting is controversial, especially in newspaper work. If reporters can operate typewriters with the accuracy necessary for an OCR reader they can probably operate keyboards producing punched tape for the computer or sophisticated visual display terminals (VDTs) on-line to the computer.

Cost is an inhibiting factor, and so is the trade union viewpoint, but it is likely that for editorial work VDTs will be increasingly used in the editing process. Copy which has been sent to the computer whether by OCR, punched tape or other means, can be recalled to a CRT unit and edited—re-written if necessary—by keyboard and scroll devices, then restored. The implications for up-dating and 'editionising' on newspapers are significant.

An interesting sidelight on the output side is the increasing interest in computer output microfiche (COM). If typesetting has been digitised within a computer (or on magnetic tape for that matter) it can be projected on to a CRT and produced as microfilm or microfiche; in some industrial and academic applications the productions of 'hard copy' (paper output) can be eliminated and microfilm produced as the only form of origination. (The use of microfilm as computer input (CIM) is possible with a special OCR unit.)

Better hardware

The original typesetting minicomputers were small, simple units with no peripherals for storage. The tendency is still to use minicomputers but as additional applications have been spotted so the need for more random access has prompted the use of more and better hardware. Disk storage and magnetic tape are now widely used and the range of input and output devices has multiplied impressively.

Some of the new applications are closely linked with the typesetting function. When setting an index, for example, it saves considerable time to set from copy presented in random sequence and leave the alphabetical sorting to the computer. The index for *Nature* is handled in this way.

Other applications are less obvious. One of the most useful developments for newspaper houses has been the joint classified advertisement setting and accounting programmes. In a typical arrangement, classified advertisement information is input by OCR to create a master classified file which in the case of a daily newspaper is output daily for publication. The necessary data are included in each input to generate an invoicing and reporting cycle.

The master file is updated daily to carry forward advertisements which are booked for more than one insertion and delete those which have expired. The computer will sort into classifications and in some cases sort alphabetically within classifications. About 32 k of memory and reasonably extensive disk storage is needed to include this sort of operation.

In July this year a team from Portsmouth and Sunderland Newspapers in the UK completed a survey² into the 'practical ideal' for a provincial daily newspaper composing systems, based on equipment in use in the USA, the UK and Europe. Composing room staff would be "much reduced", said the report. For the size of newspaper considered, editorial copy would need 12 VDTs for input and a further 7 for sub-editing purposes. Copy which was written by reporters without direct access to the VDTs would be typed on machines with OCR heads and input by way of OCR readers. (See Fig. 1 for a schematic layout of a similar system.)

The advertisement department would need 11 VDTs (including one for the supervisor); non-VDT copy would be input by OCR. Some copy would need inputting without instructions, being recalled to the VDT for typographical display. Editorial and advertisement systems would be independent but each could back up the other.

Costs and the future

The costing aspect of a hot metal system, conventional photo-setting and the practical ideal is shown in Tables 1 and 2 (from ref. 2). When extended to show the cost of increased pagination, the practical ideal is highly advantageous.

In big newspaper houses and in some large commercial printers the practice is now to centralise typesetting, accounting,

Fig. 2 A magnified 'R' reproduced by lithography from a laser-etched litho plate developed by the London College of Printing research group.

payroll, circulation data and office uses in one large computer, but the outlay is prohibitive for the smaller company.

Complete page make-up within the computer and processing through to the platemaking stage without manual intervention is the ultimate aim of much print research. With simple formats, such as those in books, this is already in general use but with complicated newspaper pages there are problems.

Make-up of a page is possible on a large CRT but the input of graphics to a totally integrated page make-up system is still in its early stages of research. Theoretically the techniques are already available. Image data processing has entered the commercial market in various guises.

The Dicom Corporation of Minneapolis produces a series of 'digital image recorders' and 'image digitisers' which can store photographs in digital form and then print them back on to film. The picture is considered as a pattern of thousands of small patches of uniform brightness—'picture elements' or 'pixels'. It is scanned to sample the light intensity of each pixel, recognising a maximum of 256 intensity levels. This information is then digitised. To reprint the picture the information is recalled by focusing a CRT spot on to film, position by position, exposure time varying with the brightness needed.

The extension of this principle to the graphics area of full-page composition is obviously possible but a very high speed of input will be necessary and a vast amount of random storage will be needed for an operation of any size.

The general view seems to be that highly sophisticated full-page make-up is feasible but likely to be extremely expensive. At the London College of Printing (LCP), William J. Jones, the head of Pre-Printing Processes, and Dick Bowmaker, who runs the computer composition section, believe cheap hardware is the key to the next move in this area. The software, they say, is possible and the techniques available. Given the ever-accelerating development of inexpensive systems engineering, we are due for the next step. Expense is, as ever, the obstacle.

The LCP is intensely aware of the critical stage print technology has reached. Dr D. J. Morantz, the Deputy Principal, says the college is "endeavouring to secure facilities to research and teach the new areas of print and communications technology". Morantz himself leads a small research team at the college and has recently developed a technique for using a laser to etch litho plates.

Lasers have been used successfully to engrave plates for the gravure process, which prints from recessed images. For litho a subtler approach is necessary in view of the need to create a surface etching suitable for the rather difficult chemical requirements of the process.

The LCP team has used an argon ion laser on a specially coated 'plate' from which they have subsequently printed by lithography with promising results (see Fig. 2, for example).

They are now looking at the production of a direct coloured image by the same process and have succeeded in etching coloured images using specially formulated coatings. To project the idea, the production of a laser-etched plate direct from digitised data might be possible.

The new print technology is quite clearly a major headache for the print unions. In the USA there have been significant local breaks with print unions which could not come to terms with new techniques. Peter Watson, Digital Equipment Corporation's North European Technical Representative, estimates a move in the USA from 70% of newspapers unionised in the pre-computer days to 40% today, with the trend continuing.

In the UK, there have been minor breaks with the principal unions concerned and some serious disruption of production as new systems have come in. The National Graphical Association (NGA), the main union concerned, is inclined to take a fairly enlightened view at national level. "We've got to come to terms with the computer", says Roy Pearson, NGA National Organiser. "I think a careful programme of re-training is one of the answers. We accept that some compositors must become computer operators and even programmers."

But as Pearson admits, the problems in practice, at local level, are formidable. Computerisation of the national press composing rooms (which is now an economic necessity) must imply a massive fall-out of compositors, and potentially boring jobs for some of those who remain. None of the English national newspapers has yet reached an agreement on the full use of computer controlled composition. The human problems are certainly likely to be bigger than the technological ones.

This necessarily short review has deliberately ignored large areas of the printing scene. It has not mentioned colour processing or machine control, in which computers are used effectively. It has omitted details of developments such as the use of photopolymer plates which make photosetting methods suitable for the letterpress printing process.

The main purpose has been to sketch out the areas in which the skill of the 'printer' is being wholly or partly replaced by the computer, for this is the most significant aspect of the subject from a technological and human viewpoint.

I have therefore concentrated almost exclusively on the role of computers in composition (although it is likely anyway that the composition process will eventually extend through to the platemaking operation). This is the area in which the most dramatic modifications are taking place, the part of the industry which is changing from craft to computer.

Minicomputers are bursting out all over

Roger Woodham

The pre-eminent position of the central computer installation to which programs and data are submitted, to emerge hours or days later, is being challenged by the minicomputer, which offers considerable computer power to individuals at the time and place they require it.

ASKING for a handy definition of a minicomputer is rather like asking the length of a piece of string: few people are prepared to commit themselves except in the vaguest of terms.

Yet minicomputers have completely changed the face of computing by making available to individuals—be they scientists, medical personnel, civil engineers or teachers—the kind of personal, 'hands-on' computing facilities that the large mainframe computer, in its cloistered and pampered surroundings, can never provide.

When pressed, however, people in the computer field will generally classify a particular computer as a 'mini' on the basis of its price. Broadly speaking, a minicomputer system costs between £1,500 and £50,000, at which price it turns imperceptibly into a 'midi', costing anywhere between £50,000

Table 1 Principal minicomputer manufacturers

Company	Market share 1974 (%)	Minicomputer revenues (\$ million)
Digital Equipment	35	410
Hewlett-Packard*	13	150
IBM*	12	145
Data General	8	92
General Automation	6	65
Honeywell	4	50
Varian Associates	3	34
Interdata	3	30
Modular Computer	2	26
Computer Automation	2	22
Systems Engineering Labs	2	18
Microdata	1	15
Digital Computer	1	10

*Includes internal installations.

and £150,000; the midis, in turn, can be divided off from the 'maxis' or 'majors', which cost more than £150,000. At the other end of the scale there is the microcomputer, the 'computer on a chip', which may cost as little as a few hundred pounds but which is so much more than a glorified hand calculator.

Growth industry

Most people would associate the name DEC (Digital Equipment Corporation) with minicomputers, and certainly that company makes the lion's share of all minicomputer sales (see Table 1). But then it was a trend setter as long ago as 1958 and has been selling its PDP series, among others, ever since. Data General, on the other hand, is the prime example of a blossoming newcomer, founded only in 1968 by a former employee of DEC who put his own ideas on the development of minicomputers into practice on his own account when DEC failed to adopt them. Since then Data General has gone from strength to strength, doubling its annual sales (which have totalled 20,000 machines in its seven years of life) every year.

During the past eight years or so, the costs of minicomputers have dropped considerably, as the price of electronic components to carry out a given function have decreased. In 1967, for example, the basic PDP8, perhaps the most widely used of DEC minicomputers, cost more than £7,000; nowadays the price of the PDP8A is little more than £1,000.

It would be a mistake, however, to think that most minicomputers are sold to individuals to use in their laboratories or offices. DEC estimates that 50–60% of its sales (by value) are not made to the final user but to another company which incorporates the computer into its own equipment, for example a mass spectrometer, where it will be used to control the operation of the equipment and process the data that emerges.

It would also be a mistake to imagine the minicomputer as simply a box that fits on to a table top and is accompanied by a typewriter input and output. That may have been the case in the late 1960s, but now a minicomputer is much more of a system, with the minicomputer proper accounting for relatively little of the cost compared with line printers, visual display units, graphics terminals, disk stores and the like.

In many ways the whole philosophy surrounding the manufacture of minicomputers distinguishes them from the larger machines. Not only do companies like Data General and DEC operate with far fewer of the trappings like prestige offices than many of the companies manufacturing mainframe computers, but the very nature of the minicomputer means that vast armies of engineers and service personnel are not required. One of the main attractions of minicomputers is

that they can be operated in the relatively dusty, humid and warm conditions of a normal laboratory or office, safe in the knowledge that they will not break down with the monotonous regularity of some mainframe machines. It is true that the criticism has been levelled against some companies manufacturing minicomputers that their after-sales service is not good, but on the whole minis seem to provide, pound for pound, much better value for money than the larger machines. One can understand why the manufacturers of big machines sometimes refer to minicomputing as 'underground computing'. It certainly gives them something to think about.

Minicomputers and scientists

Because minicomputers are tailored by their users to fit precisely the task required of them, it is difficult to generalise about the ways in which scientists use them. Almost any laboratory that requires data logging, control of equipment in real time or arithmetical calculations of any kind can profitably make use of a mini. If that mini can also be connected in to a large mainframe computer as a 'front-end machine', then the tasks

Fig. 1 This travelling computer laboratory developed at CERN contains three minicomputers, and can easily be moved from place to place.

which can be carried out (particularly 'number crunching') can be that much more sophisticated and complex.

A crystallographer, for example, might use a minicomputer system to provide views of a complex molecular structure from different angles whereas, an astronomer might incorporate a minicomputer into his telescope control equipment so that a given part of the sky can be tracked for long periods of time. Engineers, on the other hand, might well set up a mathematical model for a bridge—or an aircraft wing—and use the minicomputer to display on a visual display unit or graph plotter the consequences of certain input data (loading, sizes of beams, or whatever). Some people have found minicomputers a sufficiently attractive proposition to group them together into a travelling laboratory (Fig. 1).

The examples are so numerous that I shall describe in more detail the use made of minicomputers in a particular university department, the Department of Aeronautics at Imperial College, London. Typical is not the word to use, as no minicomputer system is typical, but certainly some of the characteristics are similar to some of those of other installations.

The department's minicomputing facilities certainly take up

rather more than a table top, a medium sized room in fact. They include the usual peripherals and in addition magnetic tape decks for data storage and the necessary equipment to link the department's facilities to the main college computer, a CDC machine. It is thus possible to collect, store and do calculations on data both locally and in the CDC machine as the need dictates.

The Aeronautics Department operates two hypersonic wind tunnels—one a 'gun tunnel' in which everything is over in 10 ms or so (but can be repeated about every 20 min) and the other a continuous low density nitrogen wind tunnel which requires accurate knowledge of flow rates, pressures and so on to establish the conditions of operation. Before the mini-computing facilities were acquired a year or so ago, the pressure profiles for the gun tunnel were recorded photographically using eight oscilloscopes and much of the subsequent data extraction was done manually. Now, however, the profiles are recorded and analysed by the minicomputer system, with the minimum of human intervention.

HELLO. THIS IS AN EXPERIMENT IN TAKING DETAILS OF MEDICAL SYMPTOMS BY A COMPUTER. IT IS DESIGNED TO HELP DOCTORS IN THEIR WORK, AND TO IMPROVE MEDICAL FACILITIES FOR THE PATIENTS AS WELL.

WE WOULD LIKE YOU TO HELP US WITH THIS AND IF YOU ARE PREPARED TO WOULD YOU PUSH THE BUTTON MARKED 'YES'. IF NOT PRESS THE BUTTON MARKED 'NO', AND IF YOU DON'T UNDERSTAND PRESS THE '?' BUTTON.

GO AHEAD AND PUSH ONE OF THE BUTTONS NOW? 0

GOOD, THANKS VERY MUCH. EVERYTHING THAT YOU SAY WILL BE TREATED IN THE STRICTEST CONFIDENCE AND ONLY DOCTORS AND NURSES WILL MAKE USE OF THE INFORMATION THAT YOU HAVE GIVEN. ARE YOU QUITE HAPPY ABOUT THIS? PUSH 'YES' IF YOU ARE, 'NO' IF YOU'RE NOT AND '?' IF YOU DON'T UNDERSTAND? 0

GOOD. THIS IS A COMPUTER TALKING TO YOU. I CAN ASK YOU QUESTIONS BUT I CAN ONLY UNDERSTAND SIMPLE ANSWERS, AND YOU GIVE ME THESE ANSWERS WHEN YOU PUSH ONE OF THE THREE BUTTONS IN FRONT OF YOU. THEREFORE ALL THE QUESTIONS CAN BE ANSWERED IN THIS WAY. DO YOU UNDERSTAND EVERYTHING I'VE SAID UP TO NOW? 0

BY THE WAY, IN YOUR JOB DO YOU EVER WORK AT NIGHTS? PRESS ONE OF THE BUTTONS NOW? 1

OK. NOW I WANT TO ASK YOU SOMETHING ABOUT YOUR CHEST. BEFORE YOU PUSH ONE OF THE BUTTONS I'D JUST LIKE TO REMIND YOU THAT IF YOU DON'T QUITE UNDERSTAND WHAT I MEAN BY THE QUESTIONS, THEN PRESS THE '?' BUTTON. TELL ME, DO YOU USUALLY COUGH FIRST THING IN THE MORNING IN THE WINTER? PUSH ONE OF THE BUTTONS NOW? 0

DO YOU USUALLY COUGH DURING THE DAY IN WINTER? PUSH ONE OF THE BUTTONS? 0

DO YOU COUGH LIKE THIS ON MOST DAYS FOR AS MUCH AS THREE MONTHS EACH YEAR? 6

OBVIOUSLY I CAN'T BE TOO PRECISE ABOUT THIS, BUT WOULD YOU SAY THAT YOU COUGH LIKE THIS ON MOST DAYS FOR AS MUCH AS THREE MONTHS IN A YEAR. PRESS YES OR NO THIS TIME? 1

WOULD YOU SAY THAT WHEN YOU GET A COLD IT GOES DOWN TO YOUR CHEST? 0

WHEN YOU GET A COLD, HOW LONG DOES IT TAKE TO CLEAR UP. FIRST, WOULD YOU SAY IT ONLY TOOK THREE OR FOUR DAYS? 1

IS IT ABOUT A WEEK? 0

Fig. 2 A conversation between a patient and a computer (from ref. 1). Replies: 1, no; 6, ?; 0, yes.

In the case of the continuous wind tunnel, it used to take up to two days to find the operating conditions by submitting data in the conventional way to the central college computer. Now they have the answer in 30 s.

As well as using the mini system for developing and testing mathematical models, for example of the behaviour of a helicopter rotor blade in various conditions, the department will also use it to control a milling machine and to develop electronic circuits. In the latter case, the computer will simulate the operation of each component that goes to make up a

circuit and thus will be used to predict the performance of the completed circuit.

Medical applications

Minicomputers are also becoming of increasing importance in medicine—both in the diagnostic field, where they are slowly but surely reshaping the traditional doctor-patient relationship, and in the laboratory, where they are increasingly relieving medical technicians of time-consuming chores. For example, colorimetric tests carried out to detect the presence of given substances in body fluids using sequential multi-channel analysers can be speeded up and made more accurate by using a minicomputer. Not only can the data be produced in a form suitable for use on the wards—a transcription process previously left to the technicians—but the analysers can be automatically recalibrated against a standard solution every so often, and an automatic correction made to all measurements as the instrument slowly and inevitably drifts away from its calibrated state. The same goes for many other instruments used to make pathological measurements.

In the case of medical interviewing by computer, the aim is to get a patient to respond to a sequence of questions about his state of health which either gives the doctor sufficient information to make a diagnosis or establishes that the patient is for some reason unable to communicate with the computer (see, for example, Fig. 1). The keeping of medical records is a whole new area again in which minicomputers seem set to spark off a revolution. It is true that hospitals have tried keeping records on large central computers before, but some schemes have come unstuck because of a reluctance on the part of doctors to write up reports in long-hand and then, perhaps the next day, rewrite them into the computer. They rightly think that is a waste of time, but could undoubtedly be persuaded to use a system which was fully accessible to them the first and only time they write up their reports and observations.

Industry and energy

The capability of the minicomputer for process control clearly has many implications for manufacturing industry, particularly as the operation of manufacturing plant in sub-optimum conditions often means that energy is being wasted. The aluminium industry is just one that has benefited from minicomputer control, in that several companies use minis to ensure that the resistance of the electrolytic cells in which the alumina is reduced does not vary, and with it the current consumption. No foreman can hope to check the voltage drop across each cell and adjust the electrode positioning sufficiently quickly that the cells operate in non-optimum conditions for less than a few minutes, and the outcome, when multiplied up, is a larger consumption of energy than necessary. Plainly any industrial process which uses any kind of control loop can profitably be linked up to a 'dedicated' minicomputer, be it steel rolling or the production of chemicals.

Decreasing size

As microprocessors come into their own, the price of minicomputers is likely to continue to fall, with the bulk of the space inside a minicomputer being taken up with connections to and from a single chip. Microprocessors are, however, likely to find their greatest application as preprogrammed computers within other pieces of apparatus. Whatever else happens, underground computing is here to stay.

Diversity of cross-bridge configurations in invertebrate muscles

John S. Wray*, Peter J. Vibert & Carolyn Cohen

Laboratory of Structural Biology, Rosenstiel Center, Brandeis University, Waltham, Massachusetts 02154

X-ray diffraction patterns from relaxed invertebrate muscles reveal the thick filament symmetries and cross-bridge configurations. The cross bridges are substantially angled to the filament axes. The results on symmetry are generally consistent with Squire's model.

X-RAY diffraction studies of striated vertebrate and insect muscles^{1,2} have not yet established the symmetry of the array of myosin cross bridges on the thick filaments, nor the configurations of the resting cross bridges. Squire^{3,4} has proposed a scheme for thick filament structure that predicts a relationship between the rotational symmetry and the diameter of the filament backbone, and on this basis has suggested possible values for the rotational symmetries of vertebrate striated and insect muscle thick filaments. These proposals are supported by recent chemical evidence^{5,6}.

We describe here the detailed low angle X-ray diffraction patterns given by relaxed striated muscles from three invertebrate animals: *Limulus* (horseshoe crab), *Homarus* (lobster) and *Placopecten* (scallop). These patterns differ from those given by vertebrate and insect muscles in one important respect; the diffraction from myosin shows sampling from the hexagonal filament lattice only on the equator. In two cases, this enables us to determine the rotational symmetries from the reflection profiles; moreover, the relative intensities of the layer lines can be used in a straightforward way to determine the configurations of the resting cross bridges. The cross bridges seem to be markedly tilted in the resting state, and to take up diverse configurations and positions. Our conclusions on thick filament symmetry are broadly consistent with Squire's model⁴.

Description of diffraction patterns

We describe here only those features of the diffraction patterns that relate to thick filament symmetry and cross-bridge configuration. Other aspects of the patterns, and full details of their analysis, will be described elsewhere.

The pattern from *Limulus* muscle has been described by us previously⁷ (Fig. 1a); it is characterised by a series of strong myosin layer lines indexing on a repeat of $3 \times 146 = 438$ Å. The first and third are the strongest of these; the fourth is of moderate intensity; and the second, fifth and sixth layer lines are weak. The meridional reflection on the 146-Å (third order) layer line has a clear subsidiary maximum associated with it, 270 Å from the meridian.

In the pattern from *Homarus* muscle (Fig. 1b) the only layer lines which can be unambiguously assigned to myosin

are those at 146 and 73 Å. These have strong meridional peaks, and the 146-Å layer line has a clear subsidiary peak 230 Å from the meridian.

The *Placopecten* muscle gives the most detailed pattern of the three (Fig. 1c); the myosin layer lines are clear and index on a repeat of $10 \times 146 = 1,460$ Å, the first strong non-meridional layer line being at 487 Å (third order), with weaker ones at 208 Å (seventh order) and 112 Å (13th order). The 146 and 73-Å layer lines are remarkably detailed; at least two subsidiary maxima accompany the meridional peak in each case, falling at different positions on the two layer lines (270 and 145 Å off meridian for the 146-Å layer line and 365 and 165 Å for the 73-Å layer line). Additional meridional reflections occur at 98 and 58 Å, which index as the third and fifth orders of $2 \times 146 = 292$ Å; these have a different profile, with no apparent subsidiary maxima.

Model calculations

We have compared the observed diffraction patterns with those calculated for model thick filaments with different helical symmetries and cross-bridge configurations. We assumed that each bridge corresponds to a single myosin molecule, and that the diffraction from the tails of the molecules (forming the filament backbone) could be neglected. A cross bridge was modelled as either a single cylinder (150 Å long \times 56 Å diameter), or as two cylinders (each 150 Å long \times 40 Å diameter) representing the two subfragment-1 (S1) subunits.

Figure 2 illustrates some relevant concepts of helical symmetry. Sections of a single type of surface lattice may be rolled up to form different multi-stranded helices (Fig. 2a); these differ in rotational symmetry (order N) and diameter, but have a very similar local geometrical relationship between neighbouring lattice points. This relationship can be determined easily from the layer line spacings in the diffraction patterns, which give directly the angular relation of one layer of cross bridges to the next (compare definition of screw order in Fig. 2). The axial translation between layers of cross bridges is within 1 or 2% of 145 Å in all thick filaments. The crucial point is that the different helices give very similar diffraction patterns, in which the different diameters are manifest only in the detailed profiles of the reflections. Qualitative aspects of the intensity distribution among the layer lines can be understood by reference to the (n,l) -plot; alignment of cross-bridge density with a particular set of helical tracks produces enhancement of the corresponding layer lines, irrespective of the rotational symmetry (Fig. 2b and c).

The following points were established by our calculations of the cylindrically averaged intensity distribution⁸ expected from helical arrays of cross bridges.

(1) The 146-Å layer line has a strong meridional peak, with a weaker subsidiary peak. For models with cross-bridge lengths

*Present address: Biophysics Institute, Aarhus University, Denmark.

Fig. 1 Low angle X-ray diffraction patterns obtained from strips of muscle about 1 mm in diameter, mounted in a cell under tension at 4 °C. Glycerinated strips (prepared as before⁷) were immersed in a relaxing buffer containing ATP; living muscles were kept in an appropriate aerated Ringer solution. A mirror-monochromator X-ray camera with a specimen-to-film distance of 400 mm was used. The X-ray source was an Elliott GX6 rotating anode loaded at 600 W. Multiple packs of Ilford Industrial G or Kodak Industrex AA film were used to record the patterns; intensity data were obtained from them by scanning on a Joyce-Loebl microdensitometer or an Optronics rotating drum scanner. Background was subtracted using scans on either side of the layer line in question; for more detailed analysis of the profiles of meridional reflections and their subsidiary maxima, Optronics scans on 25 μ m or 100 μ m rasters allowed a similar subtraction of background to be made at each point along the layer line. Reflection profiles were further corrected by deconvoluting the profile of the main beam, assumed to be Gaussian. *a*, Pattern from abdominal muscle of *L. polyphemus* (see ref. 7). up to about 200 Å, the distance of this subsidiary from the meridian depends on the radius at which the cross bridges are centred, and is only slightly affected by bridge configuration. Axial tilt (see Fig. 2) of the cross bridges weakens the meridional peak more than the subsidiary peak, so that the ratio of intensities of the two reflects the amount of tilt. The intervening minimum becomes less distinct when tilt is increased without azimuthal twisting.

(2) On the other (non-meridional) layer lines the radial positions of the maxima depend not only on bridge radius but also on rotational symmetry of the filament. The axial spacings of these layer lines are determined by the helical symmetry; the strongest layer line is that corresponding to the pitch of the myosin helix (*P* in Fig. 2*a*), and for a given symmetry and bridge radius its intensity and profile are remarkably insensitive to tilting and twisting of the cross bridges. Other layer lines are more sensitive to changes in bridge configuration, as expected from the (*n*,*l*)-plot (Fig. 2*b*).

(3) When the S1 subunits in each bridge are separated, additional effects are observed; the subsidiary maxima on the 146 and 73-Å layer lines are shifted in position, and the intensities of all the layer lines are further modulated by interference between the two subunits.

Interpretation of diffraction patterns

The spacings of the layer lines in the horseshoe crab pattern indicate that there are three layers of cross bridges separated by 146 Å in the repeat length of 438 Å (compare Fig. 2*a*). The profile of the 146-Å layer line shows that the cross bridges are centred at a radius of about 165 Å from the helix axis. The profiles of the other non-meridional layer lines are accounted for if there are three or four cross bridges at each level in the thick filament (compare Fig. 2*a*). The intensity of the 146-Å meridional is no greater than that of the first layer line at 438 Å, suggesting that the cross bridges are tilted axially, by at least 30° from the normal to the filament axis. The striking

modulation of the layer line intensities can be explained by a substantial degree of azimuthal twist of the cross bridges; combinations such as 60° twist and 30° tilt give a good fit for the profiles and intensities of layer lines 1–6 (Fig. 3*a*). With our present data, there is no need to invoke the separation of S1 subunits.

The *Homarus* pattern does not enable us to determine the symmetry of the surface lattice, but we find from the profile of the 146-Å layer line that the radius of the cross bridges from the axis is about 140 Å. The unusually small (3:1) ratio of meridional to off-meridional intensity on the 146-Å layer line indicates some axial tilt of the cross bridges. The closeness of the bridges to the axis suggests a reason for the absence of non-meridional layer lines: models with such a small radius and a high (for example, sixfold) rotational symmetry give very weak layer lines if the bridges are even slightly twisted azimuthally (compare Fig. 3*b*).

The spacings of the layer lines in the *Placopecten* pattern indicate that layers of cross bridges separated by 146 Å are related by a slightly different screw operation from that in *Limulus*: the ratio of the spacings of the strong 487 and 146-Å layer lines is here 10/3, so that the repeat length is $10 \times 146 \text{ Å} = 1,460 \text{ Å}$, although the angular relationship between 146-Å layers is only slightly different from that in *Limulus*. The screw order is defined in Fig. 2. The layer line profiles are more complex in this pattern than in the other two, but we find that the striking difference in profile between the 146 and 73-Å layer lines is well explained by certain specific bridge configurations. The bridges must have large axial extent when projected on to the axis, but the presence of clear minima in the profiles shows that this does not result from tilting single rods: instead, a good fit results when the two S1 subunits are separated axially, for example, by tilting about 20° up and 20° down, respectively. The profiles, interpreted in this way, indicate that the bridges are centred about 170 Å from the filament axis; the non-meridional layer lines can then be

fitted when the rotational symmetry is six- or sevenfold. Since the non-meridional layer lines are strong, azimuthal twisting of the bridges must be small (compare Fig. 3c). The presence of meridional reflections at odd orders of 292 Å in patterns from relaxed (but not rigor) muscles can best be explained by small axial perturbations of the bridges at alternate 146-Å levels along the filament (Millman and Bennett, unpublished).

In summary, the cross bridges in these muscles seem to lie at similar radii from the filament axes in spite of differences

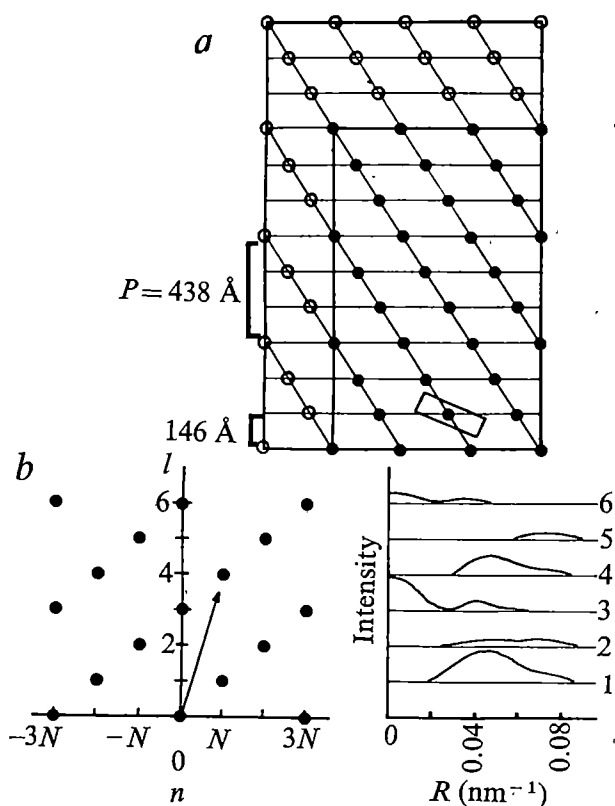

Fig. 2 *a*, Radial projections of two multi-stranded helices derived from the same surface lattice, but with differing rotational symmetries ($N = 3, 4$). The blocked area represents schematically the appearance in radial projection of a cross bridge tilted axially and azimuthally. We define axial tilt as the angle between the long axis of the bridge and the plane normal to the filament axis, and azimuthal twist as the angle (measured in this plane) between the bridge axis and the radius from the helix axis to the bridge's centre of mass. The two helices have symmetries S_3C_3 and S_3C_4 respectively, according to a notation suggested to us by D. L. D. Caspar: the notation $S_\sigma C_N$ indicates combination of a screw axis S_σ (of screw order $\sigma = 2\pi/N\phi$ where ϕ is the azimuthal rotation between units at different levels) and a point group C_N (where N is the order of rotational symmetry). Note that σ is the number of units per turn of the helix divided by the rotational symmetry; thus helices with the same value of σ but different values of N have the same local geometry in the surface lattice. Moreover, the diffraction pattern from a helix gives the value of σ directly. Thick filaments of *Limulus* have either S_3C_3 or S_3C_4 symmetry (see text); vertebrate striated muscle filaments would be S_3C_2 (Huxley and Brown's 6₂-helix model¹), or S_3C_3 or S_3C_4 (Squire's models^{3,4}). In *Placopecten* muscle, the layer line spacings in the diffraction pattern show that $\sigma = 10/3$ (see text); and the rotational symmetry is either six- or sevenfold: thus the filament has $S_3C_3C_6$ or $S_3C_3C_7$ symmetry on this notation. *b*, (n, l) -plot for the surface lattice in *a*, which describes the diffraction from any of the helices derived from it. The arrow indicates the direction in the diffraction pattern of the spike of intensity corresponding to the cross bridge orientation shown in *a*. Changes in orientation of this spike cause larger changes of intensity on layer lines far from the origin than on those closer in. *c*, Cylindrically averaged intensities calculated for the helix with $N = 3$, with single-rod cross bridges tilted 30° axially and 60° azimuthally (as in *a*). The weak second layer line, the strong fourth layer line, and the outward displacement of the peak on the fifth layer line are as expected from consideration of the (n, l) -plot.

Fig. 3 Scheme illustrating the diversity of bridge location and configuration in myosin filaments: *a*, *Limulus*; *b*, *Homarus*; *c*, *Placopecten*. The bridges at one level in each filament are shown, and the circle represents the backbone diameter as estimated from electron microscopy (see text references). Rotational symmetries for *Limulus* and *Placopecten* are those which give agreement with present data; the symmetry for *Homarus* is hypothetical (see text).

in screw and rotational symmetries. The orientations of the cross bridges vary: *Limulus* bridges, viewed as single rods, are tilted axially and twisted azimuthally; in *Homarus* they are also tilted axially, and may be slightly twisted azimuthally; and in *Placopecten* muscle there is evidence for axial splaying of the S1 subunits, with little or no azimuthal twist, and a periodic perturbation of the bridges at alternate levels.

Implications of the patterns

These are the first X-ray diffraction patterns that reveal the rotational symmetries of the thick filaments: three- or fourfold in *Limulus* muscles and six- or sevenfold in *Placopecten* muscles. Squire's model predicts a relationship between the rotational symmetry and the diameter of the filament backbone, but we have not been able to determine this diameter directly from the X-ray patterns because of limitations of the equatorial data. Electron microscope studies suggest that thick filaments of *Limulus* are about 195 Å in diameter¹⁰ whereas filaments of *Homarus* and *Placopecten* may be larger (210 and 225 Å, respectively^{11,12}). Until we obtain more precise values for the backbone diameters in these muscles, we cannot test Squire's model rigorously; but our results on symmetry, together with the values for diameters obtained by electron microscopy, seem to be consistent with his proposal on the structure of thick filament backbones.

Our results emphasise that although there seems to be a close relationship between the backbone structures in the thick filaments of different muscles, the cross bridges adopt various configurations. One similarity, however, is that in all these muscles the relaxed cross bridges are tilted away from the normal to the filament axis. If the bridges are attached to actin in a right-angled configuration before the power stroke of the contractile cycle, then some angular movement of the bridges must occur on activation or initial attachment in these muscles.

Our results on cross-bridge configuration depend on assumptions about the dimensions of the cross bridges. We have used those dimensions found for vertebrate S1 attached to actin by three-dimensional reconstruction from electron microscope images¹³. The bridges in our three relaxed muscles may depart from these dimensions, but must be elongated: we found no way of explaining the diversity of patterns other than in terms of specific orientations of rod-shaped bridges. As more precise information becomes available, our solutions will have to be revised accordingly, but we believe that the models (Fig. 3) illustrate the variety of bridge configurations required to account for the X-ray observations.

The diffraction patterns from relaxed vertebrate and insect muscles^{1,2} contain, in principle, similar information on filament symmetry and cross-bridge configuration, but the presence of sampling necessitates the use of correction factors for the meridional intensities and prevents observation of the full layer-line profiles. Sampling in the pattern from relaxed frog muscle is reduced when the muscle is stretched to a length where thick and thin filaments no longer overlap¹⁴; the fourth

layer line is then observed to be prominent, as in the pattern from relaxed *Limulus* muscle, suggesting that similar tilting and twisting of the bridges occur in this muscle. Further evidence for tilting is provided by the absence of a clear minimum on the 143-Å layer line. Squire¹⁵ reports that analysis of the sampled pattern leads to a similar conclusion.

The three invertebrate muscles we have studied possess three different regulatory mechanisms (actin-linked, myosin-linked, and double regulation¹⁶). We are now using X-ray diffraction to determine how these regulatory systems influence attachment of the cross bridges to actin.

We thank Richard Tregear for discussions and Albert Silliman for assistance in computing, and acknowledge support from the National Institute of Arthritis and Metabolic Diseases and the US National Science Foundation. ³¹P NMR studies of NADPH and NADP⁺ binding to *L. casei* dihydrofolate reductase

J. Feeney, Berry Birdsall, G. C. K. Roberts & A. S. V. Burgen

Molecular Pharmacology Division, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

The ³¹P NMR spectra of NADPH and NADP⁺ in their complexes with dihydrofolate reductase show effects from three-bond ¹H-³¹P coupling constants which indicate that the conformation about one of the C₅'-O₅' bonds changes when the coenzyme is bound to the enzyme. ³¹P chemical shifts demonstrate that the 2'-phosphate group is in the dianionic state in the complex.

DIHYDROFOLATE reductase catalyses the NADPH-linked reduction of dihydrofolate to tetrahydrofolate. As part of a wider study of the binding of ligands to the dihydrofolate reductase from *Lactobacillus casei*, we have used high resolution nuclear magnetic resonance (NMR) spectroscopy to study the complexes of NADPH and NADP⁺ with the enzyme^{1,2}. These experiments showed that both coenzymes bind tightly to the enzyme, with a stoichiometry of 1 mol per mol enzyme, and provided some evidence that a change in the conformation of the enzyme accompanies coenzyme binding.

In ¹H NMR studies of the complexes of tightly bound ligands, it is often difficult to distinguish the resonances of the bound ligand from the complicated spectrum of the protein. This problem can be circumvented by selective deuteration, or by studying nuclei other than protons. We have used ¹³C NMR to study the binding to dihydrofolate reductase of NADP⁺ enriched to 90% with ¹³C at the carboxamido carbon on the nicotinamide ring². A logical extension of this kind of experiment is to monitor the ³¹P resonance signals of the coenzyme. ³¹P is the naturally occurring isotope of phosphorus, and is relatively sensitive to NMR detection. Several other workers have used ³¹P NMR to study ligand binding to macromolecules^{3–9}, and Hoult *et al.* used this technique to study phosphorylated metabolites in muscle¹⁰. We have begun our ³¹P NMR studies of coenzyme binding to dihydrofolate reductase by examining the binary complexes of the enzyme with NADPH and NADP⁺, and the results of these experiments are reported here.

³¹P chemical shift measurements

The ¹H noise-decoupled ³¹P NMR spectrum of NADPH

(Fig. 1a) consists of two absorption bands in the intensity ratio 1:2. The low field signal (0.47 p.p.m.) arises from the 2'-phosphate group, and that at -13.78 p.p.m. arises from the two phosphorus nuclei in the pyrophosphate group, which accidentally have the same chemical shift¹¹. In the binary complex of NADPH with dihydrofolate reductase (Fig. 1b) a markedly different spectrum is observed. The 2'-phosphate resonance is shifted downfield by 2.19 p.p.m., whereas the resonances of the two pyrophosphate phosphorus nuclei are both shifted upfield, but to very different extents (0.16 and 2.65 p.p.m.). Since these latter two phosphorus nuclei are now magnetically non-equivalent, their signals appear as an AB quartet, with ²J_{P-O-P} = 20.8 Hz. The small intensity difference between the two halves of the quartet is almost certainly due to a small difference in relaxation time. At present, it is not possible to assign the two pyrophosphate ³¹P NMR signals in the complex to the two individual phosphorus nuclei. Further addition of NADPH to give a molar ratio of NADPH to enzyme of 2:1 led to the appearance of additional resonances at the positions of those of free NADPH, with no other changes in the spectrum (not shown). Clearly there is only slow exchange (on the NMR time scale) between free and bound NADPH.

Similar experiments were carried out with NADP⁺. In the binary complex of NADP⁺ and dihydrofolate reductase, the chemical shift of the 2'-phosphate resonance is identical to that found for the NADPH complex (though the ³¹P chemical shifts of this group are different in free NADP⁺ and NADPH, see below). Again, both pyrophosphate signals are shifted upfield to different extents (there is a small non-equivalence of the two pyrophosphate phosphorus nuclei in free NADP⁺; see also ref. 11). The magnitude of the larger of the two shifts is, however, distinctly less than that seen with NADPH. The chemical shifts are summarised in Table 1. The ³¹P signals from the enzyme-NADP⁺ complex are somewhat broader than those from the enzyme-NADPH complex. This is probably due to an exchange contribution to the linewidth in the former complex, as observed in earlier ¹³C studies².

In the free coenzymes, the 2'-phosphate group has a pK of 6.1 for NADPH and 6.4 for NADP⁺. The ³¹P resonance from this group shows a corresponding change in chemical shift with pH (see also ref. 11), the total titration shift being 3.9 p.p.m. (Fig. 2). In contrast, in the complexes with the enzyme the

2'-phosphate resonance of both NADPH and NADP⁺ was independent of pH within the range pH 4.5 to 7.5, occurring at a position about 1.7 p.p.m. downfield of the position of the dianionic form of the 2'-phosphate in the free coenzymes. The chemical shifts and $^2J_{P-O-P}$ coupling constant of the pyrophosphate group were also independent of pH over the same range.

³¹P-¹H spin-spin coupling constants

The remarkably narrow resonance lines ($\Delta\nu_{1/2} \sim 7$ Hz) observed in the ¹H noise-decoupled ³¹P spectra of the NADPH-enzyme complex encouraged us to examine the single-resonance ³¹P spectrum. In the single-resonance ³¹P spectrum of free NADPH

Table 1 ³¹P chemical shifts of NADPH and NADP⁺ and their complexes with dihydrofolate reductase

	2'-Phosphate	Pyrophosphate	
		A	B
NADPH (pH 6.9)	0.47		-13.78
NADPH-enzyme	2.66	-13.94	-16.47
NADP ⁺ (pH 6.9)	-0.22		(-14.47)
			(-14.15)
NADP ⁺ -enzyme	2.72	-14.32	-16.23

The chemical shifts are in p.p.m. and were externally referenced to 50 mM K₂HPO₄ solution (pH 8.0) contained in a capillary. Positive shifts to low field.

(Fig. 1d) the 2'-phosphate resonance shows a doublet splitting ($^3J_{P-O-C_2'-H} = 6.7$ Hz). No splittings can be resolved on the pyrophosphate signal, but from the line-broadening the couplings to the 5' protons must be small ($^3J_{P-O-C_5'-H_A} + ^3J_{P-O-C_5'-H_B} < 6$ Hz) (see also ref. 11).

The single-resonance ³¹P spectrum of the NADPH-enzyme complex (Fig. 1) suggests that the two phosphorus nuclei in the pyrophosphate are coupling to different extents to their corresponding 5' protons in the bound state. If reliable three-bond coupling constants could be measured this would enable us to determine the conformation about the C_{5'}-O_{5'} bonds in the bound coenzyme. Smith *et al.*¹² and others¹³⁻¹⁵, investigated the dependence of ³¹P-O-C-H coupling constants on the dihedral angle, θ , about the central bond. They found that there is a large difference in the magnitude of $^3J_{P-O-C-H}$ between *gauche* ($^3J_{P-O-C-H} = 1.8$ Hz) and *trans* ($^3J_{P-O-C-H} = 20.6$ Hz) conformations.

Unfortunately, the difference in linewidths between the ¹H noise-decoupled and single-resonance ³¹P spectra cannot be used directly to provide estimates of the coupling constants. A factor which must be considered in the measurement of coupling constants in large molecules is the possibility that rapid relaxation of one of the coupled nuclei is influencing the observed shape of the multiplets. Thus if the 5'CH₂ protons are rapidly relaxed then the measured coupling constants to the ³¹P nucleus could be smaller than the true coupling constants. The 5'CH₂ proton resonances cannot be observed in the ¹H spectrum of the coenzyme-enzyme complex which prevents us from measuring their *T*₂ values. By assuming a reasonable value for the correlation time of the complex, however, we have estimated that the *T*₂ values are in the range 0.02-0.03 s. Because of the dominant intramolecular contribution to the relaxation it is unlikely that the *T*₂ values for the two pairs of 5'CH₂ protons will be very different. We have calculated the effects of such relaxation rates on spin-multiplets with coupling constants in the range 1-20 Hz using the theory for the effects of exchange on line-shapes^{16,17}. Thus for the case of a doublet arising from coupling to such a relaxed proton when the coupling constant is 5 Hz the observed line broadening is ~ 1 Hz and for a coupling constant of 20 Hz the line broadening is ~ 16 Hz. For the high field pyrophosphate, the fact that we observe very little line broadening in the single resonance spectrum indicates that both P-O-C-H coupling constants are small (< 5 Hz); this of course assumes that our estimate that *T*₂ ≥ 0.02 s is correct. The lower field pyrophosphate shows considerable line broadening (~ 13 Hz) indicating that the sum of the coupling constants must be greater than 13 Hz (the existence of such large broadening shows that for these 5'CH₂ protons *T*₂ ≥ 0.02 s).

Ionisation state and conformation

The observation that the chemical shift of the 2'-phosphate ³¹P resonance is identical in the NADPH- and NADP⁺-reductase complexes clearly indicates that the 2'-phosphate group is binding in the same ionisation state and to the same site on the enzyme in both complexes. Since the chemical shift of this resonance is independent of pH within the range 4.5 to 7.5 in the complexes, the *pK* of the 2'-phosphate group must be

Fig. 1 a, The ³¹P proton noise decoupled spectrum of 10 mM NADPH at pH 6.9 (1,000 transients, 0.5 s acquisition time). b, The ³¹P proton noise decoupled spectrum of 1.3 mM NADPH in the presence of 1.3 mM *L. casei* dihydrofolate reductase at pH 6.9 (100 blocks of 1,000 transients 0.5 s acquisition time). c, ³¹P single resonance spectrum of 1.1 mM NADPH in the presence of 1.1 mM *L. casei* dihydrofolate reductase at pH 6.9 (319 blocks of 1,000 transients 0.5 s acquisition time). d, ³¹P single resonance spectrum of 50 mM NADPH at pH 7.9 (1,777 transients, 2.0 s acquisition time). All samples were dissolved in a D₂O buffer solution containing 500 mM KCl and 15 mM bis-Tris in the presence of 1 mM EDTA (except for sample used for spectrum (d) which contained 15 mM EDTA). The ³¹P Fourier transformed spectra were obtained at 40.5 MHz using a spectrometer (Varian XL-100) equipped with a computer (VDM 620 i). Exponential weighting functions of 0.1 s (spectrum c) and 0.2 s (spectra a and b) were used. The chemical shifts were externally referenced to 50 mM K₂HPO₄ solution (pH 8.0) contained in a capillary. The sample temperature was maintained at 11 ± 1 °C using a temperature unit V 4343.

at least three units different from its value in the free coenzyme. The position of the resonance (1.7 p.p.m. downfield from the dianionic and 4.5 p.p.m. downfield from the monoanionic form of the free coenzyme) suggests that the 2'-phosphate group binds in the dianionic form. This is confirmed by studies of the binding of 2'-AMP (B.B., J.F. and G.C.K.R., unpublished); for this compound the bound ^{31}P chemical shift is identical to that for the coenzyme complexes, and the binding constant decreases by more than a factor of ten on decreasing the pH from 7.0 to 5.5.

The decrease in pK of the 2'-phosphate group of the coenzyme by more than three pH units on binding to dihydrofolate reductase suggests that an electrostatic interaction between the phosphate group and a cationic group or groups makes a major contribution to the binding energy. Perhaps the most likely explanation of the additional downfield shift (1.7 p.p.m.) of the ^{31}P resonance from that expected for the dianionic ionisation state is that it is a linear electric field effect resulting from the proximity of a positively charged group on the enzyme. This interaction of the 2'-phosphate group presumably makes a major contribution to the hundred-

Fig. 2 Variation of chemical shift of the 2' phosphate ^{31}P resonance of NADP^+ (●, ○) and NADPH (▼, ▽) with pH. The open symbols refer to the coenzyme bound to dihydrofolate reductase and the solid symbols to the free coenzymes. The pH values are uncorrected meter readings (glass electrode) from D_2O solutions.

fold difference in the K_m values for NADPH and NADH seen for dihydrofolate reductase (J. Dann and G.C.K.R., unpublished).

The pattern of chemical shift changes for the two ^{31}P resonances of the pyrophosphate group is similar for both NADPH and NADP^+ complexes. One of the resonances is only slightly shifted in both cases; this and its $^3\text{J}_{\text{P-O-C-H}}$ coupling constants, indicate that this resonance represents the same phosphorus nucleus in both complexes. The other ^{31}P resonance shows a large upfield shift, which is significantly greater in the NADPH -enzyme complex than in the NADP^+ -enzyme complex. It is difficult to assess the significance of this difference, since we do not know the origin of the upfield shift on binding; it probably arises from a combination of

electric field effects and charge redistribution (perhaps accompanied by small changes in P-O-P angle¹⁸). ^1H NMR studies (our unpublished work) suggest that there may be conformational differences in the protein between the NADPH and NADP^+ complexes, but we cannot exclude the possibility that the difference in ^{31}P chemical shift is in some way a direct consequence of the positive charge on the nicotinamide ring of NADP^+ .

The narrow lines in the ^{31}P spectra of the coenzyme-dihydrofolate reductase complexes enabled us to measure $^{31}\text{P-O-C-}^{31}\text{P}$ spin-coupling and to observe the effects of $^{31}\text{P-O-C-}^{31}\text{H}$ spin-coupling. In experiments on other systems^{19,20}, coupling constants in the bound state were estimated by extrapolation for weakly binding ligands. The experiments described here, however, represent the first case in which direct coupling constant measurements have been possible for a ligand-protein complex.

The phosphorus nucleus giving rise to the highest-field signal shows small $^{31}\text{P-O-C-}^{31}\text{H}$ coupling constants (< 5 Hz), consistent only with a conformation in which it is *gauche* to both 5' protons. This is the conformation which is favoured for 5'-nucleotides²¹ and NADPH ¹¹ in solution. The other pyrophosphate phosphorus nucleus, which shows the smaller shift, shows a larger change in conformation differing from the *gauche-gauche* by at least 50° (based on considerations of the Karplus equation of Smith *et al.*¹²).

The conformations of NAD bound to lactate dehydrogenase²² and of ADP-ribose bound to alcohol dehydrogenase²³ are known from crystallographic studies. In both cases, the conformation about both $\text{C}_5'-\text{O}_5'$ bonds is *gauche-gauche*. For these enzymes, therefore, in contrast to dihydrofolate reductase, the binding of coenzyme is not accompanied by any change in the conformation about the $\text{C}_5'-\text{O}_5'$ bonds. At present, we are not able to specify which of the two $\text{C}_5'-\text{O}_5'$ bonds of NADPH shows a change in conformation on binding to dihydrofolate reductase, since we cannot yet assign the two pyrophosphate ^{31}P resonances in the complex. In view of the structural similarities in the coenzyme binding sites of a number of dehydrogenases^{24,25}, a comparison of the conformation of the bound coenzyme in other dehydrogenases will be of considerable interest, and we are attempting to extend our ^{31}P NMR studies in this direction, as well as studying the effects of substrate and inhibitor binding to dihydrofolate reductase on coenzyme conformation.

We thank Drs D. G. Gadian and R. E. Richards for running preliminary ^{31}P spectra, Dr R. K. Harris for the loan of ^{31}P accessories for the XL-100, C. M. Dobson for discussions, Mrs G. Ostler for technical assistance, and the Wellcome Foundation for a grant to B.B.

letters to nature

Sodium emission from long enduring meteor trains

ONE of the more perplexing atmospheric emission phenomena is the occurrence of long enduring visual meteor trains which, on rare occasions, are observed to persist for about 1 h. The mechanism responsible for the long lived luminosity is, however, elusive. Chapman¹ suggested that a source of night-time train luminosity is to be found in the store of recombination energy of free atmospheric atomic oxygen. He envisaged the role of Na atoms as continuously catalysing the transformation of atomic oxygen to molecular oxygen by sodium monoxide (NaO) formation so that the dissociation energy of O₂ was converted into sodium light with the aid of the atmospheric species O₃ and O₂. Here I examine the energetics of the sodium process and estimate the associated train luminosity.

The complete sequence of reactions is,

where the specific transitions are

At meteoric heights the atom interchange of NaO and O₃ to form NaO₂ or Na will be negligible.

When Chapman made his proposal the energetics of the various processes were not accurately known and, in particular, the exothermicity of reaction (5) was in doubt. Uncertainties arose because of the difficulties of measuring the dissociation energy, $D_0^0(\text{NaO})$, of the NaO molecule in the laboratory. Since the exothermicity of reaction (5) for producing the ground state sodium atom, Na(²S), is given by $D_0^0(\text{O}_2) - D_0^0(\text{NaO})$, then with $D_0^0(\text{O}_2) = 5.11 \text{ eV}$ the bond energy of NaO for the production of excited Na(²P) (2.10 eV) must be $D_0^0(\text{NaO}) < 66.2 \text{ kcalorie mol}^{-1}$ (3.0 eV). Although early studies indicated a lower limit to $D_0^0(\text{NaO})$ of 72 kcalorie mol⁻¹, theoretical and experimental work² has confirmed the value $60.3 \pm 4.0 \text{ kcalorie mol}^{-1}$, corresponding to $2.60 \pm 0.2 \text{ eV}$, making reaction (5) exothermic by $0.4 \pm 0.2 \text{ eV}$. The branching ratio of reaction (5) to yield ground state Na(²S) or excited Na(²P) is unknown.

Using the model that a solid meteoroid of mass $\sim 30 \text{ g}$ and velocity 40 km s^{-1} will produce a meteor with visual magnitude of about -5 , published ablation data³ can be extrapolated such that at zenith angle 30° the meteoroid will deposit meteoric atoms of linear density $\sim 4 \times 10^{17} \text{ cm}^{-1}$. With an

atomic abundance for Na of 0.5% (ref. 4) the line density of deposited Na atoms becomes $\alpha_{\text{Na}} = 2 \times 10^{15} \text{ cm}^{-1}$. The fraction of these lost in forming Na⁺ by collisional ionisation is small at the velocity of meteors.

Extensive observational data show that the heights of long enduring visual trains are confined to 85–90 km. With a molecular diffusion coefficient at the lower height for Na atoms of $4.2 \text{ m}^2 \text{ s}^{-1}$ and a radius, r , at time t of the radially expanding Na column given by $r^2 = 4Dt$ such a train will remain unresolved in a transverse direction by the naked eye for about 20 min. In such circumstances in the absence of turbulence and for an optically thin medium, the light intensity I is simply the sum of the quanta from all excited Na atoms in a cross section of the meteor train of unit length. Not only will atmospheric atomic oxygen of number density $[\text{O}_a]$ take part in the various reactions but also meteoric atomic oxygen of density $[\text{O}_m]$. With a meteoroid oxygen abundance of about 50%, then for a -5 mag meteor $\alpha_{\text{O}} = 2.5 \times 10^{17} \text{ cm}^{-1}$. For ease of computation let all species have a common diffusion coefficient and treat atmospheric oxygen as a sink, then the set of equations describing the number densities of species may be written (representing, for convenience, number densities simply by the species symbol)

$$\frac{\partial}{\partial t} \text{Na} = D\nabla^2 \text{Na} + k_5 \cdot \text{NaO} \cdot (\text{O}_a + \text{O}_m) - k_1 \cdot \text{Na} \cdot \text{O}_3 - k_3 \cdot \text{Na} \cdot \text{O}_2 \cdot \text{N}_2 - k_2 \cdot \text{Na} \cdot (\text{O}_a + \text{O}_m) \cdot \text{N}_2$$

$$\frac{\partial}{\partial t} \text{NaO} = D\nabla^2 \text{NaO} + k_1 \cdot \text{Na} \cdot \text{O}_3 + k_2 \cdot \text{Na} \cdot (\text{O}_a + \text{O}_m) \cdot \text{N}_2 + k_4 \cdot \text{NaO}_2 \cdot (\text{O}_a + \text{O}_m) - k_5 \cdot \text{NaO} \cdot (\text{O}_a + \text{O}_m)$$

$$\frac{\partial}{\partial t} \text{NaO}_2 = D\nabla^2 \text{NaO}_2 - k_3 \cdot \text{Na} \cdot \text{O}_2 \cdot \text{N}_2 - k_4 \cdot \text{NaO}_2 \cdot (\text{O}_a + \text{O}_m)$$

$$\frac{\partial}{\partial t} \text{O}_m = D\nabla^2 \text{O}_m - k_2 \cdot \text{Na} \cdot \text{O}_m \cdot \text{N}_2 - k_4 \cdot \text{NaO}_2 \cdot \text{O}_m - k_5 \cdot \text{NaO} \cdot \text{O}_m$$

$$I = \Sigma d/dt [\text{Na}(^2\text{P})] = \Sigma k_5 \cdot f \cdot \text{NaO} \cdot (\text{O}_a + \text{O}_m) \text{ photons s}^{-1} \text{ cm}^{-1}$$

where ∇^2 is the Laplacian operator in cylindrical coordinates, and an initial meteor train radius of 1 m is assumed. Such a set may be solved using an implicit finite difference scheme⁵. Na atoms are continuously cycled and no overall night-time chemical loss of Na is included. The loss-lifetime from Na⁺ formation due to charge exchange with atmospheric O₂⁺ and NO⁺ will be of the order of 10⁵ s. Some initial charge transfer of Na atoms with ions of atoms with higher ionisation potential (such as Si, Fe, Mg) might be expected. Since the initial metal ion abundances are, however, generally rather less than those of Na atoms, no significant loss will occur.

Of the reactions (1)–(5) only the three-body association (reaction (3)) seems to have been studied in the laboratory and thus is the only one for which direct measurements of rate coefficient are available. For $T = 200 \text{ K}$, and height = 85–90 km we adopt (from ref. 6) $k_3 = 2.0 \times 10^{-32} \text{ cm}^6 \text{ s}^{-1}$. Rate coefficients which appear in the literature for the other reactions are based on the values for similar processes involving N and H and we use⁶ the following; $k_1 = 10^{-13} \text{ cm}^3 \text{ s}^{-1}$, $k_2 = 10^{-33} \text{ cm}^6 \text{ s}^{-1}$, $k_4 = k_5 = 10^{-11} \text{ cm}^3 \text{ s}^{-1}$. Uncertainties of a factor of three might be expected in all rate coefficients. The rate at which

the whole chemical cycle proceeds is determined mainly by reactions (1) and (3) and therefore in part by the concentration of the minor atmospheric species, O_3 . Using the first direct mass spectrometer measurements⁷ (obtained during early evening) we used densities of 8×10^8 and $3 \times 10^8 \text{ cm}^{-3}$ at 85 and 90 km respectively. The night-time densities of oxygen used are $3 \times 10^{11} \text{ cm}^{-3}$ at 90 km, and $7 \times 10^{10} \text{ cm}^{-3}$ at 85 km. The main gas densities (cm^{-3}) used are $[N_2] = 1.2 \times 10^{14}$ and $5.0 \times 10^{13} \text{ cm}^{-3}$ at 85 and 90 km, and $[O_2] = 3.2 \times 10^{13}$ and $1.3 \times 10^{13} \text{ cm}^{-3}$ at 85 and 90 km respectively. Solutions of the set of diffusion equations were computed (see for example Fig. 1). The emission for $t < 0.1 \text{ s}$ is caused by the effect of the large initial meteoric O_m concentrations and the associated emission decay by the subsequent rapid diffusion of O_m . For times up to

Fig 1 Solutions for the case of a meteor of approximately -5 mag occurring at heights of 85 and 90 km. Branching factor $f = 0.2$. Ordinate is the photon emission rate, I , normalised to the value of $4 \times 10^{13} \text{ photons s}^{-1} \text{ cm}^{-1}$. Parameters used are: $\alpha_{Na} = 2 \times 10^{15} \text{ cm}^{-1}$, $\alpha_{O_m} = 2.5 \times 10^{17} \text{ cm}^{-1}$, $D_{85} = 4.2 \text{ m}^2 \text{ s}^{-1}$, $D_{90} = 10 \text{ m}^2 \text{ s}^{-1}$. An initial neutral atom radius of 1 m assumed at both heights.

several hundred seconds while the train remains unresolved the computed emission rates are 6.4×10^{10} and $1.7 \times 10^{10} \text{ photons s}^{-1} \text{ cm}^{-1}$ at 85 and 90 km respectively. The first point is how this emission compares with the observed train luminosities. Taking the estimate⁸ of the minimum detectable emission for the naked eye as $30 \text{ erg s}^{-1} \text{ cm}^{-1}$ and assuming that a clearly visible train is 2 mag brighter than this limit, the required emission rate in the yellow is $\sim 5 \times 10^{13} \text{ photons s}^{-1} \text{ cm}^{-1}$, indicating that the computed emissions for a -5 mag meteor fail by 7.0 and 8.3 mag. We infer that meteors of -12.0 and -13.3 mag could produce the required luminosity for 85 and 90 km respectively. The second important point is how the frequency of occurrence of such bright meteors compares with that of long duration trains. Since about 1 in 10^3 visual meteors produces a train of duration exceeding 10 s and with the observation that of those night-time trains of durations greater than 10 s in the extensive records of Olivier⁹ 1.5% had durations in excess of 30 min, then, with an observed visual rate of about 10 h^{-1} , it is inferred that the frequency of occurrence of trains longer than 30 min for a single observer is about $1.5 \times 10^{-6} \text{ h}^{-1}$. In comparison, the observed integrated flux¹⁰ of bright meteors indicates that the occurrence frequencies of meteors brighter than -12.0 and -13.3 for a single observer are 1.2×10^{-7} and $2.2 \times 10^{-8} \text{ h}^{-1}$ respectively.

If every sodium oxide reduction reaction produces an Na atom in an excited 3P state ($f = 1.0$) then at 85 km a meteor of about -10.25 mag is required to yield sufficient train luminosity. Though such bright objects certainly do produce long enduring trains⁹ the occurrence frequency of meteors brighter

than this limit is a factor of 13 smaller than the observed frequency of trains of duration in excess of 30 min. A large proportion of trains reported⁹, however, occurred during major showers particularly the Perseids and Leonids when the bright meteor flux is several times larger than the sporadic flux.

Observations of eight globular clusters at 2.3 and 4.7 μm

THE Cerro Tololo infrared photometer¹ has been used to search several globular clusters for infrared emission between 2.3 and 20 μm , principally to seek evidence for the presence of dust. Recently, more extensive observations using improved short wavelength instrumentation have been obtained at 2.3 and 4.7 μm . The latter observations were concentrated on two groups of predominantly southern clusters: (1) two globular clusters (NGC 6388 and 6441) rich in metals and suggested² to be of particular interest for the detection of gas thought to be lost from stars during the normal course of stellar evolution; and (2) six clusters with short core relaxation times and large central densities discussed³ in connection with the possible presence of massive central black holes in clusters associated with X-ray sources.

The observations at 2.3 and 4.7 μm (with bandwidths of 0.37 and 0.60 μm , respectively) discussed here were obtained on two nights in June, 1975 using the 1.5-m telescope on Cerro Tololo and an InSb detector on the dual-beamed photometer which operates at 10 Hz with an 80% duty cycle. Each cluster was carefully centred visually in the $10''$ aperture, after which precalculated offsets to the edge of the cluster were used to fix the starting point for a series of diametric drift scans. Typically, 40 drift scans in right ascension per cluster at each wavelength were obtained. As the fixed separation of $28.5''$ on the sky between the two beams (normally the 'star' and 'sky' positions) of the photometer was less than the cluster diameter, the drift scan technique actually measures an intensity gradient, and data reduction was performed on this basis. The integration time was set to equal the time to drift the beam separation distance; each drift scan therefore can be thought of as a number of discrete steps.

Table 1 lists the clusters observed, the number of scans obtained at each wavelength, the steps per scan, the total integration time per step, and the approximate apparent magnitude of each object. As each spatially resolvable point was effectively observed for only a relatively short time ($\sim 100 \text{ s}$), the detection threshold of the measurements is not as low as could be achieved by observing a single cluster-sky-point pair for a longer time. But, as one of the largest uncertainties in the theoretical^{2,3} and observational (refs 4 and 5 and M. G. Smith, J.E.H. and S. J. Shawl, unpublished) work done to date on the presence of gas and dust in globular clusters relates to the volume over which one might expect to

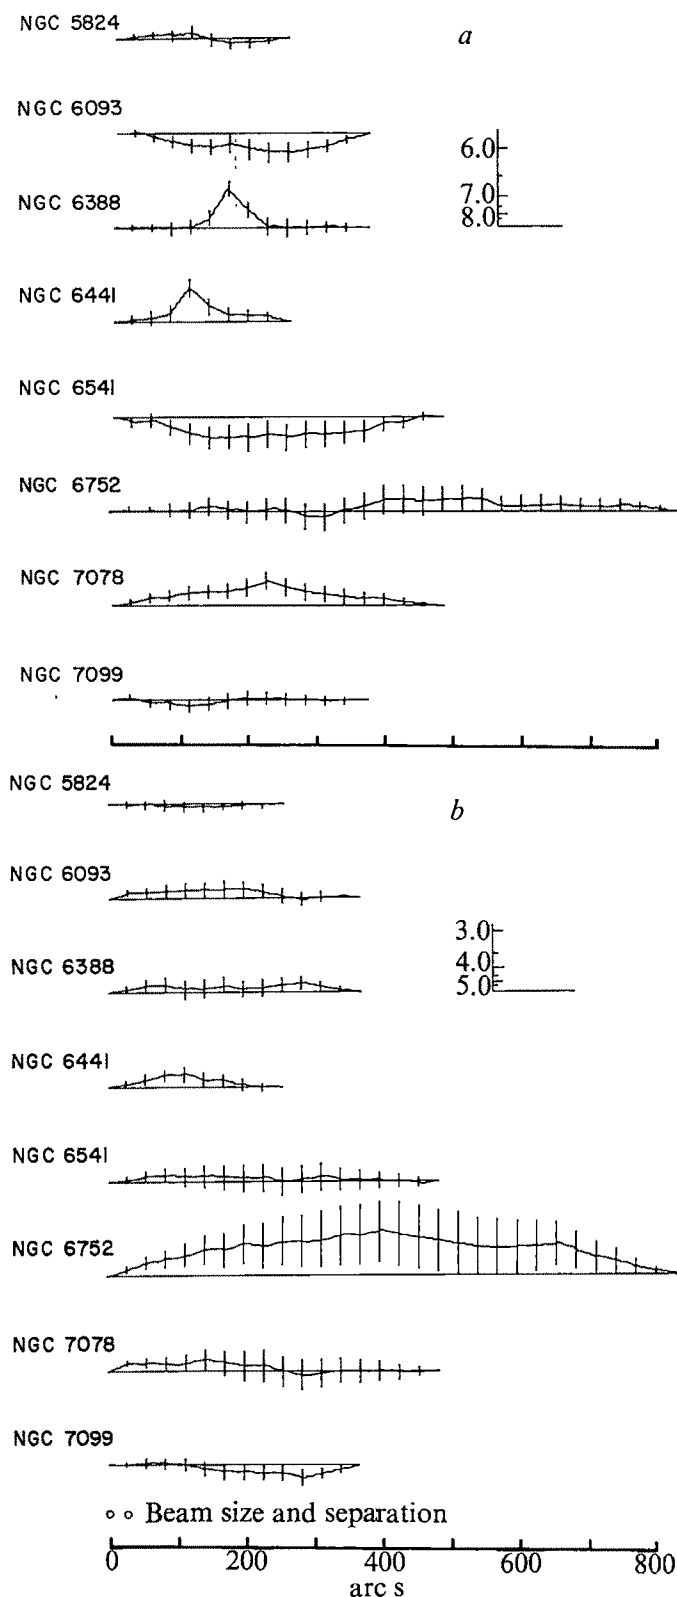

Fig. 1 Average, rectified drift scans of 8 globular clusters at 2.3 (a) and 4.7 μm (b), respectively. Error bars indicate the r.m.s. deviation among individual scans. Each point is treated separately, that is point-to-point coherence has not been invoked. The endpoints of each individual scan have been assumed to be zero; the error bars therefore decrease artificially towards both endpoints. The magnitude scale inserted in the upper right-hand corner of each figure refers to height above the baseline for a uniform brightness distribution across the 10'' aperture.

find any such interstellar material, drift scanning offered certain advantages for a pilot study such as this.

From these observations, shown in detail in Fig. 1a and b, we find that the central regions of the two massive, metal-rich clusters NGC 6388 and 6441 (refs 6 and 7) were detected at 2.3 μm but probably not at 4.7 μm. Taking the errors into consideration, the amplitude of the emission may plausibly be attributed entirely to the giants contained within the sampled volume, provided the luminosity function tabulated by Allen⁸ and the core and tidal radii derived by Illingworth⁶ and Peterson and King⁹ are applicable. Similarly, the failure to detect significant radiation at 4.7 μm is consistent with the 2.3-μm flux being due to radiation characterised by $T_{\text{eff}} > 1,000$ K. As dust would probably be cooler, the observed radiation is more likely of stellar origin. With the possible exception of NGC 7078 (M 15), all other clusters in Fig. 1 and Table 1 (which are those in the upper right-hand portion of Bahcall and Ostriker's³ figure), yield null results within the limits of this study.

Earlier observations at 2.3, 4.7, 10 and 20 μm of NGC 104 (47 Tucanae), 1851, 2808 and 5139 (ω Centauri) failed to show any emission, but the detection limits were considerably less significant than those of the more recent short wavelength observations and they have not been included here. Clearly, important clusters such as NGC 104 (massive and metal rich^{6,10}) and NGC 1851 (a transient X-ray source¹¹) deserve much closer future attention, as do NGC 6388 and 6441.

Finally, should the intriguing observation of a 10-μm emission source in NGC 7078 (M 15) (refs 12 and 13) be confirmed, the present observations may be used to set limits on the (2.3–10) and (4.7–10)-μm colour indices of the emitter.

Palaeomagnetic evidence from DSDP cores of northward drift of India

EVIDENCE of latitudinal changes associated with the northward movement of India during the Cainozoic have been described¹ from remanence inclination measurements made on sediments and basalts recovered at DSDP sites in the Arabian Sea (Fig. 1). When combined with palaeomagnetic data from continental India²⁻⁴ the results showed an initial northward movement at a mean rate of 26 cm yr⁻¹ from the Cretaceous to at least Middle Eocene times and a subsequent slower mean rate of 16 cm yr⁻¹ being resumed in the Miocene (Fig. 2a). The original analysis implied a possible pause in motion between the two phases during the Oligocene, for which period no data were available.

Further palaeomagnetic measurements have been completed by us following the recovery during Leg 24 (ref. 5) of Oligocene sediments and basalts at Deep Sea Drilling Project (DSDP) site 238 on the southern edge of the Indian Plate (Fig. 1). Only those samples considered the most stable after demagnetisation are included in the inclination values in Table 1. Palaeolatitudes from site 238 do not seem to support the phase of rapid post-Middle Miocene plate motion (Fig. 2b) but indicate instead that India may have already been much closer to its present latitudinal position by the early Oligocene.

There are several possible reasons for the discrepancy in Oligocene and post-Oligocene palaeolatitudes.

Non-verticality of coring. Inclination measurements at several sites during DSDP Leg 25 (ref. 6) indicate that the holes were never more than 5° off the vertical. Assuming a similar near verticality for the DSDP sites discussed here, errors in palaeolatitudes (probably a maximum of 2–3°) associated with non-vertical holes are, therefore, inadequate to account for the observed differences between Oligocene and post-Oligocene palaeolatitudes. There is no positive indication that DSDP site 238 has been subjected to any appreciable post-depositional tectonic tilting which would affect the observed remanent inclinations. All visible bedding relationships throughout the lower part of the core are horizontal or near horizontal.

Averaged geomagnetic field configuration other than a geocentric axial dipole. All palaeolatitudes considered so far have been calculated from mean absolute inclination values assuming a geocentric axial dipole approximation ($\tan \lambda = \frac{1}{2} \tan I$). Wilson⁷ considers, however, that the geomagnetic field for the Quaternary and Tertiary (as far back as the Miocene) may be better described by an offset dipole, the northward displacement of the dipole during these periods being 191 ± 38 and 306 ± 41 km respectively. All calculated palaeolatitudes younger than the Miocene may therefore be too far south by up to 4° as a result of this offset. Palaeolatitudes have been recalculated from mean absolute inclinations assuming a displaced axial dipole field since the Miocene (Fig. 2c). A rapid though somewhat decreased drift is still apparent for the post-Oligocene sites, requiring a 15° latitudinal change since Middle Miocene times. The offset dipole model then may account for some of the observed disagreement but the revised palaeolatitudes are still broadly inconsistent with the data from DSDP site 238.

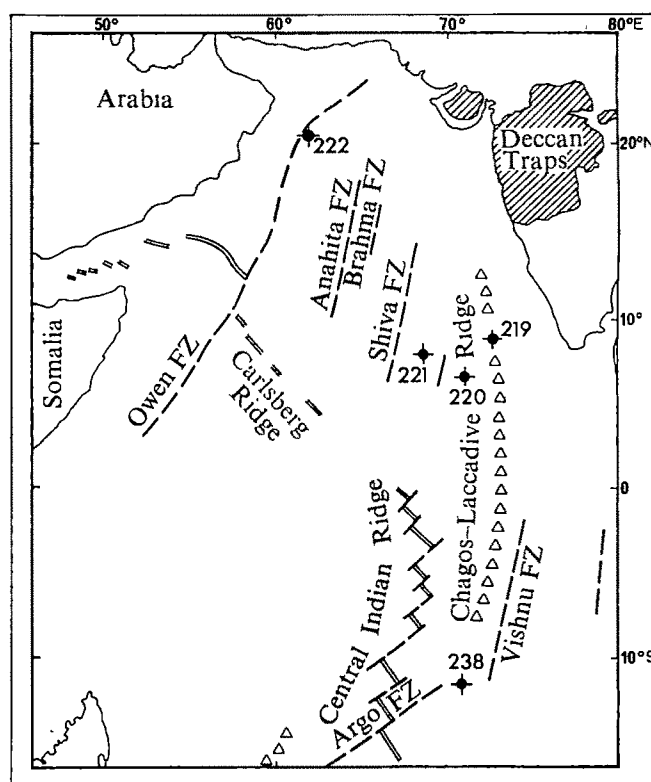

Fig. 1 Location of DSDP site 238 and other DSDP sites in the Arabian Sea which lie on the Indian Plate. FZ, Fracture zone.

Primary remanence deviations. Opdyke and Henry⁸ showed that remanence inclination errors⁹ were not present in some 52 deep-sea sediment cores. The sediments of those cores are, however, predominantly slowly accumulated pelagic and hemipelagic sediments and biogenic oozes for which average sedimentation rates of 10 m Myr⁻¹ are typical¹⁰. For current deposited deep-sea sediments, containing a predominantly terrigenous component and characterised by much faster sedimentation rates, significant inclination errors have been recorded^{11,12}. The mode of acquisition of depositional remanent magnetisation (DRM) is not yet fully understood but a shallowing of inclination might be expected due to gravitational couples (a true inclination error as defined by King⁹), or hydrodynamic tangential shearing of remanence carriers on deposition (rotation effect¹³), to post-depositional compaction, or to any combination of these. Further detailed analysis of the mean inclinations exhibited by terrigenous sediments is required to confirm the presence of such primary remanence deviations. If the possibility of significant inclination errors being associated with terrigenous sediments is acknowledged then the effect of such errors on the DSDP sediments reported here can be considered.

Sediments from DSDP sites 238 (nannochalk oozes, sedimentation rate = 12.7 m Myr⁻¹)⁵, 220 (laminated chalks, sedimentation rate = 19 m Myr⁻¹)¹⁴, and the Pliocene–Miocene sequence from DSDP site 221 (pelagic brown clay,

Table 1 Palaeomagnetic results for DSDP site 238

Site	Material	No. of samples	Age	Mean absolute inclination	Observed palaeolatitude	Reduced palaeolatitude*
238	Sediments	22	Early Miocene–late Oligocene 19–30 Myr	$30.5 \pm 3.2^\circ$	$16.4 \pm 2.0^\circ\text{S}$	$3.7 \pm 2.0^\circ\text{N}$
	Basalts	48	Early Oligocene 34–38 Myr	$28.2 \pm 1.0^\circ$	$15.0 \pm 0.6^\circ\text{S}$	$5.1 \pm 0.6^\circ\text{N}$

All errors are s.e.

*Palaeolatitudes reduced to the common latitude of DSDP site 219 according to the method of Whitmarsh *et al.*¹.

Table 2 Inclination error corrections and corresponding reduced palaeolatitudes

Site	Age	Mean inclination	Inclination error	Corrected palaeolatitude	Reduced corrected palaeolatitude
219	Upper Palaeocene	$29.1 \pm 5.6^\circ$	20.1°	$30.1 \pm 5.7^\circ\text{S}$	$30.1 \pm 5.7^\circ\text{S}$
221	Pleistocene	$15.2 \pm 5.9^\circ$	14.3°	$15.8 \pm 6.1^\circ\text{N}$	$16.8 \pm 6.1^\circ\text{N}$
222	Lower Pliocene	$22.1 \pm 4.9^\circ$	18.1°	$22.9 \pm 5.1^\circ\text{N}$	$11.8 \pm 5.1^\circ\text{N}$
Lower Siwaliks	Upper Miocene	$18.8 \pm 1.7^\circ$	16.5°	$19.5 \pm 1.8^\circ\text{N}$	$8.4 \pm 1.8^\circ\text{N}$
	Middle Miocene	$28.1 \pm 2.1^\circ$	19.9°	$29.1 \pm 2.1^\circ\text{N}$	$5.3 \pm 2.1^\circ\text{N}$

sedimentation rate = 2 m Myr^{-1})¹⁴ are of similar lithology and have sedimentation rates comparable with those sediments described above which are known to record accurately the ambient field inclination value at the time of sediment formation: mean inclinations from these sites thus provide a reliable estimate of site palaeolatitude during the corresponding stratigraphic intervals. In contrast, sediments sampled for palaeomagnetic study at DSDP sites 222 (grey detrital silty clays, sedimentation rate = $135\text{--}600 \text{ m Myr}^{-1}$)¹⁴, 219 (sandstones and siltstones, sedimentation rate $> 70 \text{ m Myr}^{-1}$)¹⁴ and the late Pliocene-late Pleistocene turbidite sequence from DSDP site 221 (silt, sedimentation rate = 170 m Myr^{-1})¹⁴ are all rapidly deposited terrigenous sediments with which significant inclination errors may be associated. An initial estimate of the magnitude of such inclination errors may be obtained by a consideration of the true inclination error predicted by the rolling spheres model¹⁵. The mean observed inclination (I_0) is related to mean geomagnetic field inclination (I_f) by the expression¹⁶:

$$\tan I_0 = 0.48 \tan I_f$$

from which the computed value of I_f has been used to calculate a revised palaeolatitude, assuming again a geocentric axial dipole model. Inclination error corrections, where applicable, together with the revised palaeolatitudes are given in Table 2. The directions of magnetisation of the Lower Siwalik detrital red shales are considered to have been acquired during deposition²: accepting a DRM origin for these rapidly deposited¹⁷ continental sediments an inclination error correction has been applied as above. All corrected site palaeolatitudes again reduced to the common latitude of DSDP site 219 are shown plotted in Fig. 2d. Allowance for inclination error effects may be seen to improve markedly the internal agreement of the palaeolatitude data from these DSDP cores. A possible overestimation of inclination errors in natural sediments by the rolling spheres model may account for the more northerly placing of the palaeolatitudes of DSDP sites 221 and 222 than is expected from their present site latitudes.

Fig. 2 Change in palaeolatitude of Arabian Sea DSDP sites during the past 65 Myr, referred to the common site latitude of DSDP site 219. *a*, Original data of Whitmarsh *et al.*¹, including the Deccan Traps (DT) and Lower Siwaliks (LS) results. □, Basalt samples. *b*, Data with palaeolatitudes determined for DSDP site 238 samples added. Also included is the Ninetyeast Ridge site 254 (ref. 20). *c*, Palaeolatitudes recalculated assuming an offset dipole approximation for the late Tertiary sites. *d*, Palaeolatitudes recalculated after application of an inclination error correction (as in Table 2).

The revised northward drift history of the Indian plate during the late Tertiary indicated by the DSDP cores described here is broadly in agreement with the Australian palaeomagnetic data^{18,19}. It provides an opportunity to qualify further the time at which the early Tertiary phase of rapid spreading ceased and the nature of the motion since that time. From the palaeomagnetic standpoint this assessment of palaeolatitudes has indicated that inclination errors may yet be of importance in certain clastic sedimentary formations.

We thank Dr R. B. Whitmarsh for his continued interest and comments. The samples were made available through the assistance of the Deep Sea Drilling Project and the US National Science Foundation. Part of this study was completed during the tenure of an NERC research studentship to R.A.B.

Seismic evidence for local undulation of olivine-spinel phase boundary

A DETAILED P-wave velocity distribution has been determined (S.D.-S. and R.A.W., unpublished) for the upper mantle in western Canada. The analysis was based on differential travel-time and relative-amplitude observations of multiple arrivals for seismograms between 14 and 40°. Three velocity models were determined for three different regions. All of these models are characterised by discontinuities at 410 and 650 km. The reflection from the 410-km discontinuity is best observed between 14 and 18°. While analysing seismograms between 14 and 18°, a group of the 410-km discontinuity. Here we present these observations and give a speculative explanation for the undulation of 410-km discontinuity. Here we present these observations and give a speculative explanation for the undulation.

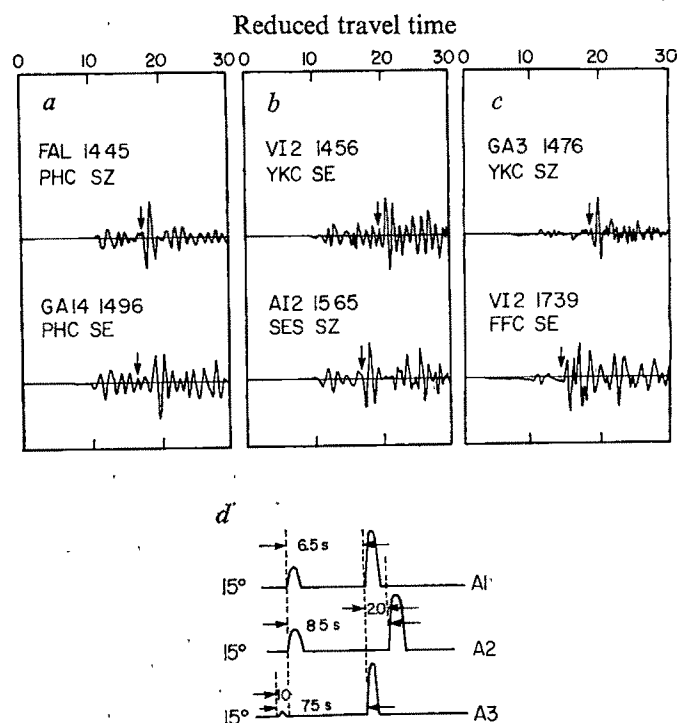

Fig. 1 Some typical seismograms of types A1 (a), A2 (b) and A3 (c) in group A (14–18°). d, Schematic representation at 15°. FAL, Faultless; VI, Vancouver Island; GA, Gulf of Alaska; AI, Alaskan Islands.

Figure 1 shows some typical seismograms around 15°, designated as group A type and subdivided into, A1, A2 and A3. The abbreviated event name and the epicentre distance are written at the top, the station name and the component of motion are written below. The name of the event roughly corresponds to its geographical location. The first arrival is always aligned at the 10.0 mark. Figure 2 shows the spatial locations of all observations. Each arrow represents the source station midpoint and the direction of the arrow indicates the direction in which the ray is travelling at its turning point. This midpoint represents the surface projection of the turning point of the ray at depth.

The amplitude ratio of second to first arrival is about 3 : 1 in A1 (Fig. 1a) and A2 (Fig. 1b) type records, in contrast to about 10 : 1 in A3 (Fig. 1c) type records. This difference in relative amplitude behaviour between A1 and A3 records was responsible for the two velocity models WCA and WCB. In model WCB, the velocity at the base of the low velocity zone is 8.4 km s⁻¹ compared with 8.17 km s⁻¹ in model WCA. This causes the first arrival to arrive about 1 s early between 14 and 18° with respect to that in WCA. As can be seen from Fig. 2, model WCA is valid for the ocean and the region near the ocean-continent boundary, whereas model WCB is valid for regions east of the Rocky Mountain trench.

The A2 type seismograms, which are similar to A1 types as far as relative amplitude is concerned, are observed

Table 1 First arrival time data for A1 and A2 seismograms for distances around 15°

Event	Station	Distance (°)	Travel time (s)	Reduced travel time at 15° (s)	Mean (s)	Seismogram type

GA14	PHC	14.96	211.6	212.10		A1

VI, Vancouver Island; GA, Gulf of Alaska.

In Fig. 2, the hatched area represents the region of Cainozoic and Mesozoic volcanic activity along with some sedimentary formations. The location of downbuckling is very close to this large scale volcanic activity. The volcanics are of the alkali-olivine type³, where olivine is generally more rich in iron than in magnesium⁴. If by localised partial melting at a depth of 410 km the olivine is enriched in magnesium with respect to the surrounding region, then it will require a higher pressure to achieve the phase transformation to spinel. Thus the discontinuity will show a local depression. This partial melting of the olivine will then generate the iron-rich alkali-olivine basalts observed on the surface. The obvious flaw in this argu-

(IOKAE) Here we present the first sedimentary province

A PRELIMINARY survey of present-day sediment distribution within the Saronic Gulf system, off the coast of Greece, has been made in support of an ongoing study being conducted by the Institute of Oceanographic and Fishing Research (IOKAE). Here we present the first sedimentary province

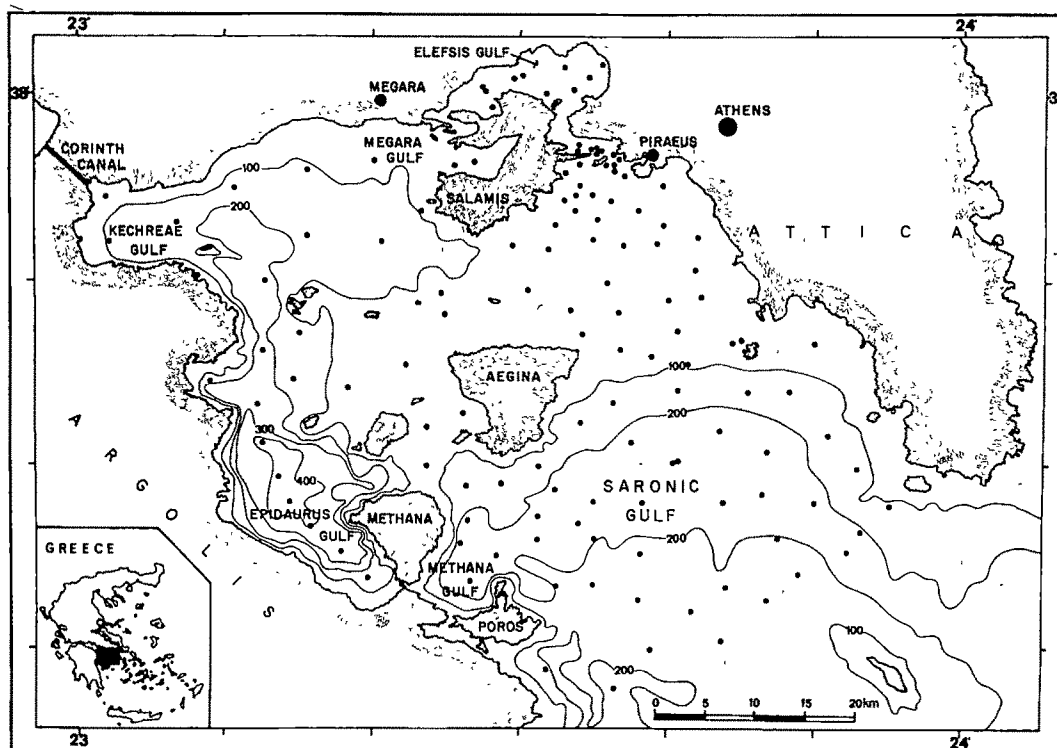

Fig. 1 Location, bathymetry and sample site map.

map of the gulf system, which expands current knowledge of the region and serves as a basis for further studies.

The only previous work of this nature done in the several gulfs comprising the Saronic system was contained in a biologic investigation by Vamvakas¹. He analysed 14 sediment samples from a limited area to determine the weight percentage of the coarse and fine fractions. Our observations confirm the results of his investigation concerning sediment characteristics and it is hoped that future research will delineate further the geological parameters and processes of the Saronic Gulf system.

The Saronic Gulf system as defined here incorporates the Saronic Gulf proper, as well as the Methana, Epidauros, Kechreae, Megara, and Elefsis gulfs (Fig. 1). It is bounded

on the west by the Argolis Peninsula of the Peloponnese, on the north and east by Attica, and opens to the south-east into the Myrtoon Sea. The seaward limit of the survey area is taken as a line from the south-eastern tip of Argolis to the southern extremity of Attica. The system has an area of 2,900 km² and, as compared with calculations by Hatzikakidis², comprises of the order of 10% of the continental shelf of Greece.

The depth of the eastern sector of the region ranges from <100 m in the Piraeus-Athens area, to between 100 and 200 m between Aegina and Attica, and is >200 m in a trough that extends from off the tip of Attica into the Methana Gulf. To the south, the depth shoals to less than 200 m. Elefsis Gulf is relatively shallow, less than 40 m

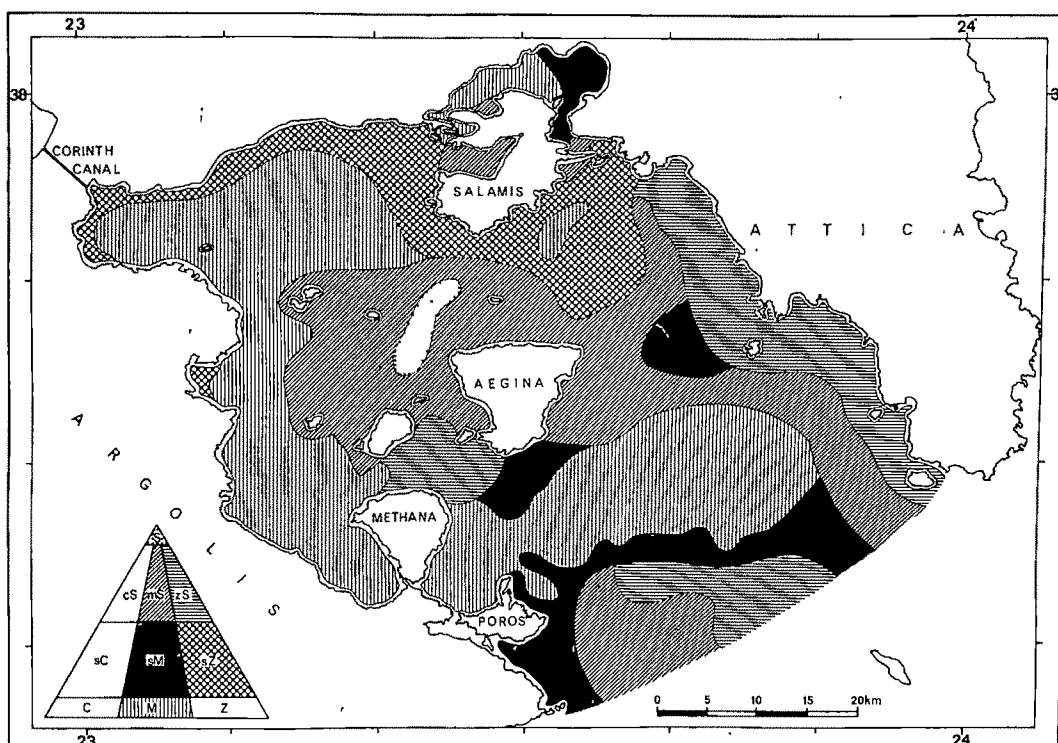

Fig. 2 Sediment distribution within the Saronic Gulf system. S, sandy; cS, clayey sand; mS, muddy sand; zS, silty sand; sC, sandy clay; sM, sandy mud; sZ, sandy silt; C, clay; M, mud; Z silt.

throughout. West of Salamis the Megara and Kechreai Gulfs exceed 100 m, and connect in the west with a north-south deep that reaches a depth of >400 m in the Epidaurus Gulf between Methana and Argolis. The Epidaurus Gulf deep and the Methana Gulf-South Saronic Gulf trough seem to bear a close correlation to pre-Pleistocene and Pleistocene normal faults, respectively, which transect the region. Further characteristics of the Saronic Gulf system have been described previously^{3,4}.

Source water to the Saronic Gulf is provided by a western boundary current in the Aegean Sea which flows past Attica into the gulf, and the annual circulation within the Saronic Gulf system has been investigated⁵. Wind generated waves are of limited fetch in all but the south-easterly direction, although seiches are occasionally generated by pressure disturbances passing over the area. Winds and barometric pressure changes contribute to a very slight Saronic Gulf tide with a range of up to 50–60 cm between the extreme high and low water marks. There are no major rivers draining into the basin and run-off from rivers and streams is insignificant except during periods of heavy, but short lived, rainfall which occur between late autumn and early spring.

The sampling programme was carried out during cruises aboard the Greek Hydrographic Service vessel *Anemos* and the Greek Navy minesweepers *Antiope*, *Niovi*, and *Phaedra*. Altogether, 131 bottom-samples were taken (Fig. 1) using Petersen, van Veen, and clamshell snapper grab samplers.

The colour of each bulk sample was determined, by comparison with the standard rock colour chart⁶. The portion of each sample subjected to particle size distribution analysis was first thoroughly mixed in a sodium hexametaphosphate (Calgon) solution (5.5 g l⁻¹), to achieve maximum dispersion. The sediment was then wet-sieved to collect the coarse, sand, fraction between 0.062 and 2 mm. The sand fraction was subsequently examined with the aid of a binocular microscope to ascertain its textural and compositional characteristics. For the purposes of this investigation an arbitrary classification was established whereby the sand fraction was called terrigenous if mineral and/or rock fragments comprised 40% or more, by estimated weight, of the fraction. No attempt was made to identify the organisms which constituted the organic component of the sand fraction (Vamvakas¹ has reported on this for the sector covered by his studies, and our 131 sand fraction samples are now undergoing species identification). Pipette analysis of the fine fraction was carried out, using 20-ml aliquots of the 4 ϕ and 8 ϕ classes at the appropriate times and depths, to determine the clay and silt content of the sample on a weight per cent basis. Based on these analyses of the sand-silt-clay ratio, each sample was then classified according to the system of Folk⁶.

It is assumed that basic factors affecting sediment distribution in this region are as follows. First, coarse terrigenous sediments, where present, are transported by wave action in coastal and shoal areas. The fine fractions settle in deep quiet waters or areas of low wave energy. Second, planktonic productivity increases toward the nutrient-rich waters in the north⁷. Benthic productivity, the main source of the biogenous coarse fraction, decreases with depth; a notable change taking place at the 200-m bathymetric contour¹. Third, yellow sediments predominate throughout the system. Where present, olive-coloured sediments denote reducing conditions caused either by poor circulation at depths or by wastes rich in organic matter, or contain ferromagnesian detritus. Finally the introduction of waste material into the system may inhibit benthic community growth and/or add fine particulate matter to the water column.

Figure 2 shows the sediment distribution within the Saronic Gulf system based on the locations of our 131 samples.

The investigation outlined here was conducted under the aegis of the Institute of Oceanographic and Fishing Research in Athens, with the cooperation of the Greek Navy and the Greek Hydrographic Service. M.L.S. was also supported by the Fulbright-Hays programme. We thank George Marinos, Ilias Mariolakas, Fotini Dousgou, and Joy Dabney for assistance.

Stress on the bottom of an estuary

MANY estuaries are sufficiently deep relative to their maximum fetch that even in severe storms the bottom remains undisturbed by wind-generated waves. Yet observations of sediment transport and of changes in benthic animal populations indicate that agitation of the bottom of deep estuaries is not infrequent (refs 1–3, and D. C. Rhoads, unpublished). We report here an analysis of current meter records which shows that such bottom disturbances can arise because wind stress at the surface causes increased turbulence deep in the water column and, consequently, a more frequent occurrence of unusually high velocities near the bottom.

The records analysed were obtained at two locations along the central axis of Long Island Sound (LIS), an estuary 150 km long, 32 km wide at the widest point and with a mean depth of 17 m. The dominant water movement in LIS is the resonant co-oscillating tide⁴; tidal stream speeds reach 30 cm s⁻¹ at the locations studied. Currents were recorded with two types of meters: type I meters recorded instantaneous measurements of water velocity at time intervals which may be set from 1 to 30 min. Type II meters recorded the average speed and direction over successive 20-min intervals. All the meters were operated on taut moorings and were set 2 m above the bottom. The recorded velocities have been resolved into E–W and N–S components, approximately parallel and perpendicular to the axis of the estuary. Each time series of velocities is decomposed into a constant term, a group of periodic terms, and a fluctuating term. The periodic components have been removed from the velocity records by a least-squares regression of 18 sinusoids of tidal periods. The constant term is defined as the mean velocity over 3 or 12 h, depending on the time period chosen for calculating the variance or standard deviation. The residue remaining after removal of the mean and periodic parts is described as the fluctuating component, u' .

Wind data have been obtained from the US National Weather Service station at Stratford Point (41°10'N, 73°08'W), an exposed location on LIS. The data consist of 3-min averages of speed and direction, recorded every 3 h.

Figure 1 is a polar histogram of u' calculated from a record made by a type I current meter at Station A (41°09'N, 72°48'W,

depth=23 m) sampling the flow every 5 min for 4 d. The fluctuating velocities are isotropic. The square of the wind speed, proportional to the wind stress, and the standard deviation, σ_x , of u_x' over 3-h intervals are compared in Fig. 2a. The wind was from the north throughout the period of observation. Increases in wind stress result in increases in σ_x but the peaks of σ_x lag those of the wind stress by about 5 h. The time series of the E-W and N-S components of u' are quantitatively similar, as expected from the results in Fig. 1.

Two additional sets of data were obtained by sampling the current less frequently over a period of nearly one month at station B (41°08'N, 72°53'W, depth = 23 m). A type I current meter sampling every 30 min, and a type II meter were used. Wind stress data and σ calculated for 12-h periods are shown

Fig. 1 Histogram of 951 observations of the fluctuating velocity component, u' , at station A. Darkest shading, probability of an observed velocity being in a box is $5\% < P \leq 7.5\%$; intermediate shading, $2.5\% < P \leq 5\%$; lightest shading, $0 < P \leq 2.5\%$. There is apparently no dependence of u' on direction.

in Fig. 2b and c. During calm weather σ drops to the range $1.5\text{--}2\text{ cm s}^{-1}$ identified as characteristic of the turbulence in the undisturbed tidal stream. Small increases in wind stress do not have much effect on σ but winter storms raise it by as much as a factor of 4 above the level associated with the tidal stream alone. The increase appears to be slightly smaller and the background somewhat higher for the type II meter, a consequence of the 20-min averaging performed in the meter itself. The magnitude of σ in the two data series in Fig. 2b and c is insensitive to wind direction. No correlation between u' and the phase of the tide is evident in the records.

That the observed increase in u' does not result from disturbance of the meters by orbital motion of waves on the surface is shown by two lines of evidence: a water pressure recorder (wave gauge) was operated during the period February 19–March 27, 1975 on a reef at 41°00'N, 73°25'W, in water 14 m deep. Records of pressure fluctuations caused by waves on the surface were obtained when the wave period exceeded 4 s. (The recorder is insensitive to waves of shorter periods because of the large hydraulic attenuation.) There is a close correlation between the amplitudes of the pressure fluctuations and the factor v^2/f_m where v is the wind speed, f is the fetch for the

wind direction and f_m is the minimum possible fetch at the site. Throughout LIS large values of f/f_m occur only in the ENE direction. Pressure fluctuations at the recorder are detected only for easterly winds. The fetch in all other directions is too short to allow waves of long period to develop, even for very strong winds. All of the current meters operated in water deeper than that in which the wave recorder was placed so that, if disturbed by waves, the disturbance would occur only for easterly winds. In fact, σ_x and σ_y depend only on the wind speed; they are independent of wind direction. Examination of the magnitude of u' during the major storm of December 14–17, 1972 illustrates that point: strong winds from the ENE, which produced a storm surge with an amplitude of 1.2 m on December 15 were followed by WNW winds which produced a negative surge of 1 m. The magnitude of σ is significantly greater when the WNW winds are prevailing, at times when waves with long periods are absent.

A second line of evidence comes from the observation that the magnitude of u' is isotropic, as shown in Fig. 1, in the record obtained at location A. During the entire period covered by that record the wind direction was constant (from the north). Any direct contribution to u' from wave action should be greatest in the direction of wave advance, which is not observed.

The current meter records show that during periods of high wind stress the frequency of occurrence of high velocities near the bottom is increased. For example, $\sigma = 3.4\text{ cm s}^{-1}$ for the second 8.3 d of the record in Fig. 2b and the probability of occurrence of $|u'| > 10\text{ cm s}^{-1}$ is found from the distribution curve in Fig. 3 to be less than 1%. During the stormy period, the first 8.3 d of the record, $\sigma = 6.7\text{ cm s}^{-1}$ and the probability of encountering $|u'| > 10\text{ cm s}^{-1}$ increases to 12%. In an estuary the average kinetic energy resulting from storm-generated turbulence may be small compared to that generated by the tide, but the more frequent occurrence during storms of speeds greater than the maximum speed of the tidal stream, V , will have a large influence on processes characterised by a critical speed $v_c > V$ (processes such as the transport of the coarser fractions of the sediment). Very large speeds, such as

Fig. 2 Time series of σ (heavy lines) and the square of the wind speed (light lines). a, σ_x for a type I meter at station A with the wind speed advanced to lead the current by 5 h; b, σ_x for a type I meter at station B; c, σ_y for a type II meter at station B.

Fig. 3 Distributions of E-W fluctuating velocity components from the combined records of two current meters operating simultaneously 1.5 km apart at station B. Solid histogram data from an 8.3-d stormy period beginning on December 14, 1973; heavy dotted histogram, data for the subsequent, calmer 8.3 d; the solid and dotted curves show the normal distributions with the same mean and variance for each period. Each histogram contains 800 observations.

2V or 3V, are also much more likely to be encountered in storms, with a consequent disruption of benthic animal communities, even though the latter may be well below the depth directly affected by waves.

The data used here were obtained in studies for the New England Division, US Army Corps of Engineers and the United Illuminating Company of New Haven, Connecticut.

First marine Triassic fauna from the Antarctic Peninsula

THE fauna reported here was obtained from the Legoupil Formation in the north-western part of the Antarctic Peninsula (Fig. 1), which has been assigned a Cretaceous age on the basis of radiometric data^{1,2}. Among the first collection of poorly preserved fossils from this formation were two bivalves tentatively referred to the Cretaceous genus *Platopsis*, an identification which substantiated the radiometric evidence. The study of a more recent collection, by members of the British Antarctic Survey, shows, however, that the bivalves have strong Triassic affinities and, since there is no reason to suspect that they are derived, indicates that the Legoupil Formation is of the same age.

It is also noteworthy that the sandstones and greywackes of the Legoupil Formation are lithologically and structurally unlike other known Cretaceous sequences in western Antarctica, more closely resembling rocks of the Trinity Peninsula 'Series'³⁻⁵ of possible late Palaeozoic age⁶⁻⁷. Both formations crop out in close proximity in the area discussed here, and the two have been confused in the field when the same outcrops have been assigned to both formations by different investigators^{2,3}. That reflects the similarity of the two rock groups and casts doubt on whether they are really distinct.

As yet, marine invertebrate fossils are unknown from the Trinity Peninsula 'Series' proper, and those from the Legoupil Formation are only known from a belt 100 m wide on the Duroch Islands (Fig. 1). The fauna is dominated by bivalves which occur mostly as moulds and are usually concentrated in

thin beds or decalcified coquinas. In spite of their unpromising state of preservation, several specimens still show sufficiently fine detail in the hinge region to allow reasonably confident identifications of following: *Myalinella* (?) sp., *Bakevelloides* aff. *hekiensis* (Kobayashi and Ichikawa), *Hoernesia* (?) sp., and *Neoschizodus* sp. nov.

Other fossils include a possible fragment of an inarticulate brachiopod, a gastropod, a serpulid, and some possible arthropod tracks.

Stratigraphically, the two most important species are *Bakevelloides* aff. *hekiensis* and *Neoschizodus* sp. nov. (Fig. 2). The best specimen of *Bakevelloides* (Fig. 2a) shows the ligament pits and pseudotaxodont dentition found in the type material⁸, but the dentition is better developed than in *B. hekiensis* which it otherwise resembles closely. Most species of *Bakevelloides* described seem to occur in the Upper Triassic of Asia. *Neoschizodus* sp. nov. (Fig. 2b) is the commonest element in the fauna. It shows typical myophoriid dentition and has a prominent myophorous buttress. It is closely related to the widely distributed *N. laevigatus* (Ziethen) of Lower to Middle Triassic age, but differs in having a radial riblet on the posterior area, and in possessing striations on some teeth. No specimens that

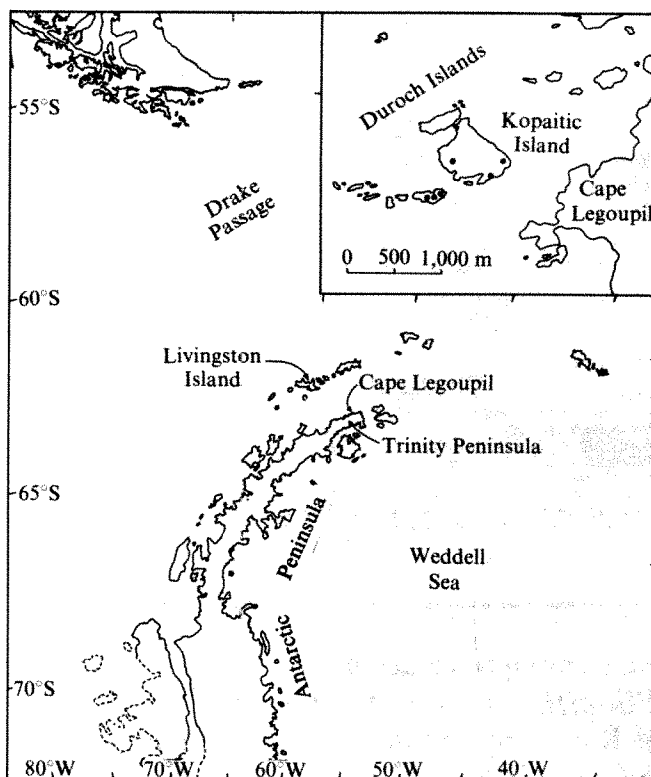

Fig. 1 Map of the Antarctic Peninsula showing the location of Cape Legoupil; inset, fossiliferous localities on the off-lying Duroch Islands (solid circles).

could be referred to *Platopsis* (?) sp. were identified among the collection. The only illustrated example of that species^{1,2} compares closely with the specimens here referred to *Neoschizodus*, and it is suggested that earlier ascriptions to *Platopsis* resulted from a misidentification.

This fauna provides the first evidence of marine Triassic rocks in the Antarctic Peninsula. The only previous fossil evidence for Triassic deposits in western Antarctica came from the discovery of poorly preserved plant fossils on Livingston Island¹⁰ but these were not collected *in situ*. Because of the close lithological and structural similarities between the Legoupil Formation and the Trinity Peninsula 'Series', it now seems possible that the upper age limit of the latter rock group could be younger than envisaged previously. Some tenuous supporting evidence has been cited from Livingston Island,

Fig. 2 Fossils from the Legoupil Formation: a, *Bakevellioidea* aff. *hekiensis* (Kobayashi and Ichikawa); b, *Neoschizodus* sp. nov.: a, anterior adductor muscle scar; cs, cardinal socket; l, ligament pits; m, myophorous buttress; p, pits along palial line.

where poorly preserved macroplant remains occur in the Miers Bluff Formation, previously correlated with the Trinity Peninsula 'Series' of the Antarctic Peninsula. That material suggests an age later than Carboniferous, perhaps even Mesozoic¹¹.

A detailed account of the fauna from the Legoupil Formation, and its implications, will be published elsewhere¹².

New ramapithecines and *Pliopithecus* from the Lower Pliocene of Rudabánya in north-eastern Hungary

THE increasing interest of specialists in problems of human evolution has involved not only the final phases, which are well documented but not satisfactorily settled, but also the critical examination of earlier phases. For the latter, however, researches rely mainly on the Indian *Ramapithecus*¹ and the East African *Kenyapithecus*² maxillary fragments, while almost entirely neglecting the corresponding European materials. The reason for this may be that the European finds were scattered specimens, or insufficiently described and therefore very difficult to evaluate. In addition, they are described under too many, probably superfluous, names.

To fill this gap we here provide some preliminary data concerning recently found corresponding materials from Hungary. At the same time, however, we emphasise that for a more complete survey of the whole problem it will also be necessary to take the important fossil anthropoid materials from Spain³ and those found recently in the Near^{4,5} and Middle East.

There were two earlier finds in the Carpathian Basin, in East Alpine localities: Dévény-ujfalu (now Devínska Nova Vés, Czechoslovakia)^{6–9}, and St Stephan in Southern Austria¹⁰. A

very rich Lower Pliocene site, Rudabánya in north-eastern Hungary, recently yielded anthropoid material. The fossil-bearing strata belong to the lignitic Pannonian (Lower Pliocene) limnic sediments overlying the karstic depressions and valleys of the Lower–Middle Triassic range of the Rudabánya Mountains impregnated by a metasomatic iron ore body. The Pannonian strata contain, apart from the primate specimens, a very rich vertebrate fauna, a good mollusc fauna and a very rich flora (details of which will all be published elsewhere). The locality was rediscovered as an outstanding site of fossil hominoids by Mr G. Hernyák, chief geologist of the Iron Ore Works of Rudabánya, who has also collected the most important hominoid remains.

The flora indicates Mediterranean-subtropical climatic condition with traces of zonation ranging from aquatic through wet forest to grassland and higher mountain elements respectively. The basically Lower Pliocene character of the vertebrate fauna is proved by the presence of *Hipparion* in the fossil material. That it is a *Hipparion* fauna of archaic character is confirmed by the persistence of Miocene insectivore elements (*Trimylus*, *Miosorex*, *Dimylechinus*, *Plesiodimylus*, *Galerix*, *Lantanothierium*), the three hominoid forms, and especially the Miocene *Pliopithecus*, cricetids of Mio-Pliocene transitional type (*Cotimus*, *Democricetodon*), varied amphicyonids (*Amphicyon*, *Agnotherium*, *Rudacyon* n.g.), definitely Miocene carnivores (*Semigenetta*, *Sansanosmilus*), or archaic lagomorphs (*Amphilagrus*). At the same time, forms typical of younger *Hipparion* faunas are entirely missing, (for example, *Mesopithecus*, *Chalicomys*, *Neocricetodon* "Kowalskia") and especially all kinds of murids, hystricids and leporids, or ictitheriines, hyenas, true *Machairodus* forms, large agriotheriids (*Indarctos*, *Agriotherium*, *Agriarctos*), among ungulates primarily suids of 'Microstonyx' type, varied antelopes and all gazelles. All this evidence indicates that the fauna resembles that of Eppelsheim (Eppelsheimian), but certainly antedates it (Bodvaian) and thus should be dated as more or less synchronous with the invasion of *Hipparion* in Europe.

The anthropoid material is from 20 individuals (84 teeth altogether and 18 postcranial fragments) representing three different forms. One is a *Pliopithecus* species of great size

(*Pliopithecus hernyáki* Kretzoi^{11,12}). The other two are pongo-hominids: *Rudapithecus hungaricus* Kretzoi 1967¹³⁻¹⁸ and *Bodvapathecus altipalatus* Kretzoi 1974^{11,12}. Brief information about the hominid materials is given in Tables 1 and 2.

The main characteristics of the new *Pliopithecus* species and the two pongo-hominids respectively are the following:

1. *Pliopithecus hernyáki* Kretzoi 1974^{11,12}. A species of the genus *Pliopithecus* s.l. of big size, with rounded pentagonal P₄, strong labial cingulum on the molars and well developed posterior fossa (triangular in M₃) with disto-lingual notch. The crest on the axial side of the protoconid (where it should meet the corresponding crest of the metaconid) is missing. Dimensions: D₄ 8.2-5.5 mm, P₄ 5.9-6.4 mm, M₁ 7.8-6.5 mm, M₂ 8.5-6.8 mm, M₃ 10.2-6.3 mm. Holotype: Rud-9 (Fig. 6)—The Rudabánya species seems to represent an independent superspecific taxon beside the described subgenera *Pliopithecus* s.str., *Epipliopithecus* and *Plesiopliopithecus*, for which the name *Anapithecus* n.sg. is suggested.

2. *Rudapithecus hungaricus* Kretzoi 1967¹³⁻¹⁸. A hominoid of slight build with a short face; high symphyseal, parasagittal, section of premaxillaries; wide incisive canal; flat palate; subparabolic dental arc; relatively small I¹; premolars subequal in size; low, brachyodont postcanines without cingula. Length of M₁-M₃: 29.5-31.0 mm. Holotype: Rud-1 (Fig. 1a, b), paratype: Rud-12 (Fig. 2a-d).

3. *Bodvapathecus altipalatus* Kretzoi 1974^{11,12}. A robust form of bigger size than *Rudapithecus*; high vaulted palate; relatively hypsodont post canines with marked cingula, roughly sculptured, thick enamel surface. The dimensions of M₁-M₃ are about 37-38 mm. Holotype: Rud-7 (Fig. 4a-c), paratype: Rud-14 (Fig. 5a, b).

There are some significant differences between the holotypes of *Ramapithecus brevirostris* and *Rudapithecus hungaricus*. *Ramapithecus* has a high, vaulted palate and the cross section

of the alveolar axis of the upper canine is longer and turned outward antero-laterally. (Former authors, like G. Lewis, failed to realise that the deformed alveolus of the canine gives the false impression of an abbreviated cross section.) *Ramapithecus* has a more antero-laterally situated I² so its dental arc is not subparabolic but more broadened in the frontal part. This means that *Ramapithecus brevirostris* (not identified with *Dryopithecus punjabicus* in my opinion), in spite of its younger geological age, is in some respects more ape-like, or more primitive than *Rudapithecus*, and represents a different line of hominid evolution.

Kenyapithecus with its flat palate, deep preorbital fossa, roughly enamelled and cingulated, higher-built postcanine dentition and somewhat bigger size, differs significantly from both *Rudapithecus* and *Ramapithecus*, in spite of the fact that most recent authors consider it identical to the Siwalik speci-

Fig. 2 *Rudapithecus hungaricus* Kretzoi, left upper jaw fragment, Rud-12. a, Lateral; b, occlusal; c, frontal; d, aboral view (×1).

Table 2 Postcranial hominoid remains from Rudabánya

No.	Specimen	Determination
1	Distal fragment of left humerus	? <i>Rudapithecus</i>
2	Caput of the left femur	? <i>Rudapithecus</i>
3	Distal end of left femur	? <i>Rudapithecus</i>
4	Proximal end of left tibia (most probably of the same specimen)	? <i>Rudapithecus</i>
5	Left astragalus, without head	? <i>Rudapithecus</i>
6	Distal end of metapodial	
7	Distal part of phal. I	? <i>Rudapithecus</i>
8-9	Medial fragments of phal. I	? <i>Rudapithecus</i>
10-11	Distal parts of phal. II	? <i>Rudapithecus</i>
12	Distal two-thirds of phal. I	? <i>Bodvapathecus</i>
13	Distal part of phal. I	? <i>Bodvapathecus</i>
14	Phal. I, proximal end missing	<i>Pliopithecus</i>
15	Distal half of phal. I	<i>Pliopithecus</i>
16	Diaphysis of phal. I	<i>Pliopithecus</i>
17	Medial fragment of phal. I	<i>Pliopithecus</i>
18	Proximal end of phal. III	? <i>Pliopithecus</i>

Fig. 3 *Rudapithecus hungaricus* Kretzoi, right mandibular corpus, Rud-17. a, Lateral; b, occlusal view ($\times 1.4$).

men. In addition to the differences between *Kenyapithecus* and *Ramapithecus*, *Rudapithecus* has, as distinct from *Ramapithecus*, an even flatter palate, in this respect resembling *Kenyapithecus*.

When comparing our material with anthropoid material considered to be such on the basis of their measurements, the situation is complicated by their poor preservation. We, therefore,

Fig. 4 *Bodvapihthecus altipalatus* Kretzoi right maxillary fragment, Rud-7 (type). a, Occlusal; b, aboral; c, lateral view ($\times 1.4$).

limit our comparison to the remark that the femur of the *Paidopithecus rhenanus*—reconstructed by mistake to about one inch longer than its real size—cannot actually differ greatly from *Rudapithecus*. It is not impossible, however, that the much-debated femur of *Paidopithecus rhenanus* is closer in size to the forms represented by the M_3 named *Neopithecus branconi* or the small molar referred to as '*Rhenopithecus*'. The scantiness of the *Hispanopithecus laietanus* and *Udabnopithecus garedziensis* materials make satisfactory comparison impossible. Apart from patterns common to all ramapithecines, or representing only the general trend of hominisation, there is no close relationship between *Bodvapihthecus* and the forms mentioned above, although the construction of its palate resembles *Ramapithecus* and its general dental trend *Kenyapithecus*. The two recently described finds from the Balkans (*Grecopithecus freybergi*⁴ and

Fig. 5 *Bodvapihthecus altipalatus* Kretzoi, right mandibular fragment, Rud-14. a, Lateral; b occlusal view ($\times 1.5$).

*Dryopithecus macedoniensis*⁵) are larger and thus differ from both ramapithecines found in Rudabánya. Finally, *Dryopithecus keiyuanensis*, *Sivapithecus africanus*, *S. occidentalis* and *Rahonapithecus sabadellensis* ought to be mentioned and compared with our material as pongo-hominid forms tending towards hominisation. Because of their fragmentary representation or even lack of description, however, they are not really suitable for comparison. The same is also true of the remains described under the names of, for example, *Dryopithecus punjabicus*, and *Bramapithecus thorpei*. In these circumstances the most useful solution is to retain the identifications derived from well-preserved materials, suitable for further comparison, until the more correct names can be more precisely defined, hopefully, on the basis of further and richer material.

Although the taxonomic status of *Rudapithecus* is not influenced by its relationship to the forms representing the later phase of hominisation, it should be mentioned. The facial structure of *Rudapithecus* evinces a trend of hominisation which indicates a straight line of evolution through forms like *Pithec-anthropus modjokertensis* (restricted to the Sangiran IV maxillary) towards *Homo*. This seems to make it probable that australo-

Fig. 6 *Pliopithecus hernyáki* Kretzoi left mandibular fragment with D₄-M₃, Rud-9 (type). Occlusal view ($\times 2$).

pithecines represent a close side branch with their independent development (decrease in size of front teeth, enlargement of molars, and so on), in many respects surpassing *Homo sapiens*, but not finally achieving the *Homo* level of evolution.

On the basis of the preliminary examination of the pongo-hominids of Rudabánya we can state the following conclusions: (1) Hominisation did not originate in certain isolated and more or less small tropical-subtropical gene pools, but was an evolutionary trend covering the whole Afro-Eurasian faunal radiation with its pongo-hominids. (2) Extant anthropoid apes, on the other hand, achieved their present non-human phase and trend of evolution as a result of a more or less extreme forest dwelling specialisation developed in certain isolated, tropical forest areas in Central Africa and south-east Asia. (3) Anthropoid evolution tending towards hominisation obviously developed on different levels, in numerous parallel, more or less 'human' branches which evolved so many parallel patterns during the process that it is not easy at present to find among them the single line which leads to the evolutionary development of *Homo sapiens*—and perhaps this is not even our primary concern at the moment, being more interested in collecting basic data. (4) The difficulties of identifying the previous, not satisfactorily defined, taxa make it necessary to use for the time being, the well-definable, later established taxonomic names.

I thank Mrs L. Pellérdy for photography.

Tilt aftereffects with subjective contours

CELLS in the visual system respond well to spatial discontinuities in luminance (edges), but they are poorly activated by diffuse light¹. It has been proposed² that the selective response of edge-detectors to properties such as orientation and motion underlies form and pattern perception. In these terms, local discontinuity within the visual display is a necessary condition for perception of an edge. There are, however, anomalous contour effects³ (see examples in Fig. 1a and 1b) in which edges are clearly visible at sites where the visual stimulus is homogeneous. Such edges have been called subjective or cognitive contours on the supposition that cues to apparent depth within the display lead the observer to infer that he is seeing one plane located in front of, and interrupting, another plane^{4,5}. In these terms, "Since every plane must have an edge, the bounding contour is supplied by the perceptual system . . . a subjective contour is simply the edge of a subjective plane, and a

Fig. 1 Edges are visible within (a) and (b) in the absence of local luminance discontinuity. (b) was used as the subjective contour stimulus in the experiment. Test measures were also obtained following inspection of (c) and (d); these displays were used as control conditions in that they do not yield subjective contours but have some real contours in common with (b).

subjective plane is a surface which ought to be present on the basis of available depth cues, but is not except in the mind of the perceiver."

We report that the tilt aftereffect, in which a vertical line appears displaced clockwise after exposure to an anticlockwise tilted line, can be induced with subjective contours as well as with edges defined in terms of luminance discontinuity. In addition, exposure to a real contour results in a tilt aftereffect when the orientation of a subjective contour is subsequently judged, and vice versa. As the tilt aftereffect is generally attributed⁷ to adaptation of neural detectors which are tuned to contour orientation, these results raise the question of whether the perception of subjective contours has a basis at least in part in the activity of sensory feature detectors.

The experiment established the extent to which a test contour appeared displaced from vertical as a consequence of exposure to contours tilted 0°, 15°, 30°, 45° or 60° anticlockwise from vertical. This range of values was used because of evidence that the size of the tilt aftereffect depends on the difference in orientation between the inspection and test lines⁸. Aftereffects were measured for four conditions: inspection with real contour, test with real contour (R-R); inspect real contour, test subjective contour (R-S); inspect subjective contour, test real contour (S-R); inspect subjective contour, test subjective contour (S-S). The real contour, a white bar on a black ground, subtended either 4°36' \times 12' (inspection stimulus) or 3°4' \times 12' (test stimulus). The display shown in Fig. 1b was used to induce the subjective contour, which appeared in inspection and test conditions as a white bar subtending 4°36' by 12'. The top and bottom sections of this bar were

correlated with real contours, but the centre section subtending $3^{\circ}4'$ was visible in the absence of local luminance discontinuity.

On each trial a centrally located fixation point was shown for 2 s, then the inspection bar for 1 s, and finally the test bar for 100 ms. The observer's task was to report whether the test bar appeared tilted clockwise or anticlockwise from vertical; the use of other response categories was not permitted. The orientation of the test bar was varied over trials by a double-random staircase with 1° steps. For each of the four observers eight staircases were completed at the five inspection orientations for the four stimulus conditions. The order of testing conditions across observers was controlled by a Latin square, and orientation sequences were varied randomly between observers and conditions.

Figure 2 shows, for each stimulus condition, the mean orientation (displacement from true vertical) at which there was equal likelihood that the test bar appeared tilted clockwise and anticlockwise. The size of the aftereffect is given by the difference between values obtained when the inspection bar was vertical and those found after exposure to a tilted bar. An analysis of variance based on difference scores calculated for each observer showed that test judgments varied significantly as a function of the orientation of the inspection bar ($F(3,9)=32.30$, $P < 0.01$). The trends are consistent with other data⁸ on the orientational selectivity of the tilt aftereffect. The size of the aftereffect was independent of whether the inspection or test bars were formed by real or subjective contours ($F(3,9)=2.68$, $P > 0.05$), and the interaction between the orientation of the inspection bar and the type of display was also insignificant ($F(9,27)=0.86$, $P > 0.05$).

The possibility needs to be considered that judgments for condition S-S, S-R and R-S were under the control of the local luminance discontinuities within the display used to induce subjective contours instead of the spatial properties of the subjective contours themselves. It should be recognised that these two variables cannot be studied in isolation; the presence of real contour information is a necessary condition for the induction of subjective con-

tours. It is possible, however, to measure the apparent tilt of real and subjective test bars after inspection of patterns (such as those shown in Fig. 1c and d) that do not yield subjective contours although they have some real contours in common with Fig. 1b. Measures obtained in such control conditions differed significantly from the largest after-effects obtained for conditions S-S, S-R and R-S. The four subjects also judged the real and subjective test bars after adaptation to Fig. 1b without the broken circle at the centre, the broken circle alone, Fig. 1b with a complete circle at the centre and eight dots arranged as a bar. Mean displacements ranged from $+0.41^{\circ}$ to $+1.22^{\circ}$; all values were significantly less than the largest aftereffects shown in Fig. 2. These results can be treated as weak main effects rather than as control data in that the adaptation displays other than the eight-dot stimulus yielded slight subjective contours.

Our results indicate that the tilt aftereffect can be generated with subjective as well as with real contours. The orientational selectivity of the aftereffect is similar for the two types of stimulus. In addition, the apparent orientation of an edge that is correlated with luminance discontinuity can be shifted by previous exposure to a phenomenal edge at a location within the display that is uniform in luminance. In recent accounts neural edge-detectors have been implicated in the perception of real contours, whereas subjective contours have been treated as products of cognitive or inferential operations. Although data indicate^{9,10} that subjective contours cannot be explained within a simple sensory theory, our results suggest that it is premature to attribute the perception of real and subjective contours to fundamentally different processes.

Fig. 2 Mean location at which a test bar appeared vertical after exposure to an inspection bar tilted from 0 to 60° anticlockwise. Measures are expressed relative to true vertical, with clockwise displacements given negative scores and anticlockwise displacements positive scores. Values are shown separately for the four display conditions described in the text. ●, R-R; □, R-S; ■, S-R; ○, S-S.

Ambiguous cognitive contours

CONTOURS perceived in the absence of physical gradients of stimulation have been called cognitive contours¹, subjective contours^{2,3}, contours without gradients⁴, anomalous contours⁵ and quasi-perceptive margins⁶. The phenomenon is produced by placing inducing elements in special arrangements on a surface of uniform luminosity, as in Fig. 1. A whiter-than-white triangle can be seen overlying three black disks and a white background. The apparent brightness difference and the perceived contours extending between the disks are illusory. Gregory¹ discusses two paradigms, the cognitive and the physiological, which have been used to explain these contours. We introduce here two configurations which support the cognitive paradigm.

Figure 2 presents a subjective contour configuration which is perceptually ambiguous. Whereas Fig. 1 produces only one set of illusory contours (those corresponding to the 'sides' of the triangle), the 'ship's wheel' configuration can be perceptually organised in various ways, each resulting in an arrangement of illusory contours unique to that organisation. Three objects can be differentiated in the wheel-shaped structure of the figure; +, × and ○. These stratify in depth in a specific manner for any particular organisation of the figure. For example, the + can be seen overlying the ×, which in turn overlies the ○. The

Fig. 1 A standard subjective contour configuration: a phenomenally complete triangle is perceived overlying three black disks.

bars of the + and the × are seen to pass over the ○, with illusory contours extending across it. The relative positions of these objects may spontaneously reverse, with the ○ now appearing on top. Curved illusory contours demarcating the phenomenal borders of the ○ are then seen extending across the bars of the + and ×. Alternatively, the + may be seen overlying the ○, and both of these overlying the ×. In this case, the straight subjective contours of the + are seen passing over the ○, and the curved subjective contours of the latter are seen passing over the ×. Clearly, there are as many possible arrangements of illusory contours as there are possible alternative organisations of Fig. 2, and the contours will be observed to 'shift' about the display during the transition from one organisation to the next.

Figure 3 presents another ambiguous subjective contour display. Illusory contours corresponding to the inside corners of a six-pointed 'star' may be seen extending between adjacent disks. Alternatively, an upright triangle can be seen overlying an iden-

Fig. 2 The ship's wheel configuration: the +, × and ○ alternate in apparent depth over time, thus causing the subjective contours corresponding to the phenomenal 'edges' of these objects to shift about the display. Subjective contours are not seen if the central white region is perceived as a completely solid object localised entirely in one plane (for example, a ship's wheel).

tical, but inverted, triangle. In this case, the subjective contours of the upright triangle are seen to proceed in straight lines, cutting across the 'corners' of the inverted triangle as they do so. If the relative positions of the triangles reverse, the subjective contours of the inverted triangle will now seem to cut across the corners of the upright triangle.

Corresponding brightness effects are associated with the alternative organisations of Figs 2 and 3. Objects which are seen as overlying other objects (or backgrounds) are perceived as somewhat brighter. For example, when the ○ is seen on top in Fig. 2 it seems somewhat brighter than the + and ×. Similarly, when the upright triangle is topmost in Fig. 3, it seems brighter than the inverted triangle which it overlies, and the latter, in turn, seems brighter than the background. When the perceptual organisation reverses the relative positions of the objects, the brightness relations reverse as well.

Since Figs 2 and 3 consist only of specially arranged inducing elements on white surfaces otherwise perfectly uniform in luminosity, the perceived contours and brightness effects are, of

Fig. 3 The star configuration: either a six-pointed star or two superimposed triangles (with one inverted) may be seen. The perceived location of the illusory contours depends on the prevailing perceptual organisation.

course, illusory. The important point, however, is that different perceptual organisations of the same figure generate different illusory effects. Consequently, any theory which attempts to account for subjective contours must accommodate the fact that these phenomena are not totally stimulus-bound: that is, what is seen in Figs 2 or 3 cannot be predicted simply from a knowledge of the luminosity distribution of the physical array. Since physiologically oriented theories of subjective contours are often stimulus-bound in this sense⁷, they cannot explain our findings. The view that perception is a process of hypothesis formation in which 'object hypotheses' are selected by, but go beyond, sensory data⁸ is, however, consistent with these findings. If a configuration presents sensory data which can support multiple object hypotheses (Figs 2 and 3), then shifting illusory contours would be predictable as the result of alternative hypotheses being sequentially tested and applied to the ambiguous array.

There are two major limitations of the cognitive theory. First, the theory cannot predict which specific object hypothesis, of many possible, will be selected in a given instance. Second, the cognitive theory has not attempted to explain the brightness differences which are consistently observed in subjective contour configurations. Competing theories often start by explaining the brightness differences first, and then derive the contours from the apparent brightness gradients which result^{7,9}. Cogni-

tive theory holds that it is the formation of object hypotheses going beyond sensory data which gives rise to subjective contours, so it must be shown that the associated brightness effects arise concurrently with, or subsequent to, the formation of the contours, rather than casually preceding them. We would argue that the apparent brightness differences derive from a classic figure-ground phenomenon: that is, a figure will generally seem brighter or more intense than a background of equal reflectance value¹⁰. In so far as the central white area in Fig. 1 is conferred the status of an object (triangle), it will necessarily be seen as figure overlying a background. Consequently, its brightness will be enhanced and a whiter-than-white triangle will be perceived. This would also account for the reversals in apparent brightness seen in Figs 2 and 3 which arise when the perceptual organisation reverses the relative positions of objects in the display. As one object becomes 'figure' relative to another by overlying it, it will also take on a phenomenally brighter or more intense appearance¹¹.

Development of cat visual cortex following rotation of one eye

EVER since the first description of the optical inversion of images within the vertebrate eye, philosophers and psychologists have pondered the question of how animals interpret the directions of objects in space. The physiological discovery of retinotopic 'maps' in the brain (such that the retina is represented in an orderly array in the tectal¹ and cortical² visual areas) seemed to provide an answer to the question. Neurones in these visual centres have receptive fields that are restricted to a particular region of the retina and could therefore preserve information concerning the positions of objects in the visual world.

Humans show considerable ability to compensate for prism-induced displacement³, partial rotation⁴ and even complete inversion⁵ of the retinal image. The physiological mechanisms underlying this capacity are not understood. On the other hand, amphibians never adjust their orienting behaviour to adapt to physical rotation of the eye⁶. Indeed, if the optic nerve

is severed at the time of rotation, the fibres regenerate and reinnervate the contralateral optic tectum, re-establishing the original relationship between retina and tectum and thus an inverted representation of the visual world⁷. These experiments suggest that lower vertebrates have a rigidly specified mapping system to the contralateral optic tectum, which is uninfluenced by visual experience, whereas in higher mammals visuomotor behaviour is responsive to alteration of the visual input. In fact in kittens initial acquisition of visually co-ordinated behaviour, such as guided locomotion and guided

Fig. 1 The kitten (K131) whose right eye was surgically intorted by 109°.

reaching, requires visual experience with feedback from movement⁸.

We have developed a technique for torsional rotation of the cat's eye (without sectioning the optic nerve, since it will not regenerate). The results of this procedure have provided information about the plasticity of visual localisation in cats, and about the genetically specified restrictions on the properties of cortical cells.

In three kittens less than 3 weeks old, one kitten that had been kept in total darkness until 5½ weeks old, and one normal adult, the insertions of all the extraocular muscles of the right eye were divided and the whole globe gently intorted, taking care not to stress the optic nerve or the blood supply to the eye. In each case the eye remained in its new position without suturing, and the conjunctiva healed very rapidly. Within a few days partial muscle reattachment occurred and limited eye movements returned.

All animals were then housed in a colony room (illuminated for 18 h each day), with both eyes open. Several weeks later the animals' vibrissae were cut and their visuomotor coordination was tested, using diffusing contact lenses to cover each eye in turn. Their behaviour was entirely normal through the non-rotated left eye and Table 1 summarises tests of their visual abilities through the rotated eye alone.

In all but one of these animals, with the normal eye occluded, head and eye movements could be elicited by presenting a small, high contrast object against a homogeneous background (visual following). Except in K108, the animal with the smallest amount of rotation (30°), however, the movements

Table 1 History of the animals and visual abilities using the rotated eye alone

Animal	Age at rotation	Age at recording	Angle of intorsion of right eye	Visual following	Visual behaviour using the rotated eye "Triggered" visual placing	Visually guided reaching	Guided locomotion
K108	11 d	20½ weeks	30°	+	+	+	—
K126	21 d	19 weeks	72°	+	+	—	—
K140	Adult	5 weeks later	106°	+	+	—	—
K131	16 d	17 weeks	109°	+	+	—	—
K137	38 d (previously dark-reared)	11 weeks	115°	—	+	—	—

+, Visual behaviour present; —, Visual behaviour absent.

Fig. 2 Preservation of approximate retinotopic projection in the kitten (K131) shown in Fig. 1, whose right eye had been intorted by 109° . The electrode penetration through the visual cortex of the right hemisphere is reconstructed in the lower half of the figure, and the locations of four binocularly driven cells are marked on the track. Above are diagrams of the positions of the receptive fields of these cells, as they appeared on the screen in front of the animal. The centre of each field is marked \bullet and they are joined, in series, with interrupted lines. The projections in space of the true retinal vertical and horizontal meridians are drawn as solid lines, intersecting at the projection of the area centralis. The upper visual field of each eye (the field of the inferior retina) is marked \rightarrow , labelled 'up', on the projection of the vertical meridian.

were rather jerky, unlike the smooth tracking seen in normal cats. Although the gross sequence was usually in the correct direction, the individual jerky movements may have contained inappropriate components, which were corrected by later movements. This unusual strategy of tracking deserves further study using more exact techniques for observing eye and head movement.

When lowered towards a broad horizontal surface, every cat extended its forelimbs downwards at an appropriate

of rotation, the responses were not very accurately directed in space. The lack of complete visuomotor compensation is, perhaps, not surprising in view of not only the rotation itself but also the relative immobility of the operated eye and the conflicting information from the other eye.

Behavioural compensation might be more complete with a longer interval between operation and testing, or if the normal eye were closed from the time of rotation. Both of these expectations seem to be confirmed by more recent experiments: two

Fig. 3 Analysis of the interocular similarity of preferred orientation for 44 binocular cells from kittens with eye rotation and 33 from the adult animal. The receptive field orientation was measured on retinal coordinates¹³ and, for each unit, the algebraic difference between the preferred orientations in the two eyes gave the value plotted on the abscissae of the histograms. Cells with identical orientation preference on the two retinæ have a value of zero. The distribution for the kittens, which had not had previous prolonged normal binocular vision, is significantly broader than that for the adult control ($P < 0.001$, F test, d.f. 43,32). The variance is not accounted for merely by pooling of data from several animals, since individual kittens showed very wide variability in the differences in preferred orientation.

distance from the surface ('triggered' visual placing). In normal cats such triggered extension is elicited only by approach to a horizontal surface: however, except for K108, movement of the limbs in the same direction sometimes also occurred if these animals were brought near a vertical surface.

K108 showed visually-guided reaching. When tested with an interrupted surface of the type introduced by Hein and Held⁹, this animal reached accurately for the prong, and avoided the gaps between prongs. In contrast, the animals with larger angles of rotation were equally likely to place the paw on a prong or in a gap. Finally, none of the animals managed consistently to avoid objects when moving through an obstacle course (guided locomotion). The results of eye rotation in the adult cat (K140) were not obviously different from those in kittens with comparable angles of rotation.

Thus the rotated eye was able to mediate behaviour to visual input, but, except for the animal with the smallest angle

of rotation, the responses were not very accurately directed in space. The lack of complete visuomotor compensation is, perhaps, not surprising in view of not only the rotation itself but also the relative immobility of the operated eye and the conflicting information from the other eye.

Behavioural compensation might be more complete with a longer interval between operation and testing, or if the normal eye were closed from the time of rotation. Both of these expectations seem to be confirmed by more recent experiments: two cats tested more than a year after 90° rotation are much more adept when using the rotated eye alone than any of the cats in the present study. A further animal with a 90° rotation that had the lids of the other eye sutured showed the best behavioural recovery of all, having quite reliable tracking movements, excellent performance on the obstacle course and accurate visually guided reaching.

vast majority of neurones were orientation selective, just as in the visual cortex of a normal cat¹¹. Only 5 out of 147 cells in the kittens and 0 out of 44 cells in the adult were unresponsive to our visual stimuli.

Photographs of the slit-shaped pupils taken before the preparation (see Fig. 1) and after paralysis enabled us not only to measure the surgically induced intorsion of the right eye (assuming that the two pupils should have been symmetrically orientated), but also to assess any further rotations of the eyes induced by paralysis. Thus we were able to relate the position and preferred orientation of each receptive field to the corrected horizontal and vertical meridians, on true retinal coordinates.

Most cells in our adult cat, as in normal animals¹¹, were excited by stimuli shown to either eye (35 out of 44 cells). Not surprisingly, however, the majority of visually responsive neurones in the younger animals (95 out of 142) were monocularly driven, just as in kittens with a surgically induced lateral deviation of the eyes¹².

The retinotopic map of the rotated right eye was virtually unchanged. Each region of the cortex represented approximately corresponding areas of the two retinæ, just as it had before rotation. Figure 2 shows the results for one animal (K131) whose right eye had been intorted by 109°. The histologically reconstructed microelectrode penetration is drawn below, and above it, just as they appeared on the screen, are the positions of the receptive fields of four binocularly driven neurones recorded at the points marked by filled circles on the reconstructed electrode track.

The projections on the screen of true horizontal and vertical retinal coordinates, intersecting at the area centralis, are shown for each eye. For this sequence of neurones the receptive fields in both eyes shifted from the vertical meridian, slightly into the field of the contralateral hemiretina, and then far out into the field of the ipsilateral hemiretina, typical of a penetration that starts in area 18 and moves deep into area 17. The other units recorded in this penetration, which were mainly monocular, had receptive fields that fitted this general progression. In every animal we observed this preservation of the normal retinotopic mapping from the rotated eye, and recently we have confirmed the finding in another kitten with a sample of receptive fields extending more than 30° into the peripheral retina.

Binocular cells in these kittens tended to have similar receptive field properties on the two retinæ in spite of the fact that there was no possibility of regular correlated binocular input after the rotation. In particular, we measured the preferred orientations on true retinal coordinates and Fig. 3 shows histograms of the differences between the two receptive fields for all binocular neurones that had clear orientation selectivity in both eyes (44 cells from the kittens, 33 from the adult). Cells from the normal adult with eye rotation had very closely matched preferred orientations on the two retinæ just as in normal cats¹³. Cortical cells in the kittens (who had not experienced a prolonged period of binocular vision before eye rotation) also, on average, had similar orientation preferences on the two retinæ. The range of differences (approximately $\pm 70^\circ$) was, however, much greater than in normal animals.

Thus there seems to be a definite innate restriction on the mapping from retina to visual cortex and, to some extent, on the interocular similarity of preferred orientations of cortical cells. Certainly the visually controlled behaviour displayed by cats with one eye rotated cannot be attributed to a reorganisation of the relationships between retina and visual cortex.

This work, and the visits to Cambridge of C.K.P. and A.H. during 1973, were supported by a grant to C.B. from the Medical Research Council and by a grant from the Spencer Foundation to A.H. R.C.V.S. held a Special Fellowship from the US National Institutes of Health.

We have recently learned that Yinon, Auerbach, Blank and Friesenhausen¹⁴ have also found binocularity to be reduced in the visual cortex of cats after rotation of one eye.

Light-induced formation of dense-core vesicles in rod photoreceptors in retina of *Xenopus laevis*

SEVERAL attempts have been made to correlate changes in the fine structure of synaptic regions of vertebrate photoreceptor cells with dark or light adaption¹⁻³. Synaptic vesicles in both rods and cones were reported to be reduced in size after prolonged exposure to darkness^{1,2}. Later workers³⁻⁵, however, have not substantiated these claims. Mountford³ did not find any changes in vesicle populations in photoreceptors in response to changes in illumination; neither did Cragg⁴, although he did find that receptor terminals increased in width after prolonged periods in the dark, and decreased in width after only 3 min of exposure to daylight. Wagner⁵ showed in fish retina, that in animals kept under a constant day-night regime, the numbers of synaptic ribbons were reduced in fish fixed towards the end of the night period.

The upshot of this previous work is that there are no unequivocal descriptions of changes in vesicle structure which can be correlated with changes in illumination. We were therefore intrigued to find changes in the morphology of vesicles in the synaptic region of rods in the retina of *Xenopus*, brought about by exposure to continuous light. In the rods of toads kept in normal day-night conditions, or in constant darkness (up to 12 d), the synaptic vesicles surrounding the ribbons and in the neighbouring cytoplasm were all agranular (Fig. 1a). On the other hand, in animals kept under constant illumination (0.5 m distant from a

Table 1 This shows the mean % of dense-core vesicles in the synaptic vesicle population associated with synaptic ribbons relative to the period of exposure to continuous illumination

4	24.55 \pm 2.38	$\left. \begin{array}{l} \ll 0.001 \\ 0.01 \end{array} \right\} P$
9	51.30 \pm 3.36	
12	13.88 \pm 3.29	

P is the probability between different treatments calculated by Student's *t* test. *P* > 0.05 not significant.

Fig. 1 Electron micrographs of rod pedicles of *Xenopus* retina from animals exposed to: *a*, day-night cycle; *b*, 4 d; *c*, 9 d; and *d*, 12 d continuous light. In (*a*) note that the three electron-opaque synaptic ribbons are surrounded by a cloud of exclusively agranular, synaptic vesicles. By contrast dense-core vesicles are present alongside the ribbons (curved arrows) in (*b*), (*c*) and (*d*) and in the cytoplasm (straight arrows) in (*b*) and (*c*). In (*c*), the open arrow indicates a clump of dense-core vesicles where the plane of section has just grazed a synaptic ribbon. In (*d*) note the absence of agranular vesicles from one side of a synaptic ribbon (straight arrow). Material prefixed in glutaraldehyde, postfixed in osmium tetroxide and embedded in epoxy resin. Scale line applies to all parts of the figure.

240 V, 40 W pearl, tungsten bulb; illuminance = 86.08 lx) after 4 d dense-core vesicles were found alongside the synaptic ribbons and in the surrounding cytoplasm (Fig. 1*b*, Table 1). By 9 d, on average, just over half the vesicles associated with the ribbons had dense cores (Table 1), although in some sections through synaptic ribbons all the vesicles were the dense-core variety (Fig. 1*c*). Dense-core vesicles were also more common in the rod cytoplasm (Fig. 1*c*). Another interesting feature in many rods was the presence of what appeared to be glycogen particles (Fig. 1*c*). After 12 d in the light, the number of dense-core vesicles was drastically reduced compared with that after 9 d (Table 1). Moreover, some agranular vesicles were lost from around the ribbons (Fig. 1*d*). Our results therefore suggest that constant illumination over several days induces the rods to produce dense-core vesicles, but interestingly enough, no similar structural changes in vesicles have been seen in the cones.

What physiological activities could underlie the appearance of these dense-core vesicles in rods? It is possible that because vertebrate photoreceptors are hyperpolarised by light⁶, that this will reduce their rate of neurotransmitter release⁵. In these conditions it might be expected that the

transmitter stores would increase. Such an increase in the transmitter store may account for the appearance of the dense-core vesicles and for their progressive increase in number during 9 d. The drop in their number by 12 d is puzzling, but it could be attributed to metabolic changes within the rods associated with a cessation or reduction of transmitter synthesis. This could also account for the reduced numbers of agranular vesicles associated with some of the synaptic ribbons (Fig. 1*d*).

The identity of the neurotransmitter(s) in rods and cones is not known⁷, although amino acids, catecholamines and acetylcholine are all possible candidates for synaptic transmitters in the retina⁸. Turtle photoreceptors can synthesise acetylcholine⁹, and there are high levels of taurine in the photoreceptor cells of the frog retina¹⁰. The occurrence of dense-core vesicles in the rods of *Xenopus* appear to be inconsistent with the presence of either of these two substances, since this type of storage vesicle is thought to be indicative of indoleamine and catecholamine stores in neurones⁸. Recent fluorescent and electron autoradiographic studies have demonstrated that although monoamines are present in the retina, they do not reside in the rods and cones⁸. It has been reported, however, that a fluorescent amine is associated with the nuclear layer of rods and cones¹¹, although the authors discounted that the fluorescence was caused by monoamines known to be neurotransmitters, that is dopamine, adrenaline and 5-hydroxytryptamine. The presence of an unidentified amine in the photoreceptors while possibly supporting our structural evidence of dense-core vesicles in the rods, conflicts with our failure to demonstrate dense-core vesicles associated with the synaptic ribbons of cones. It could be argued, however, that because cones are less sensitive to light than rods, the level of illumination in our experiments was insufficient to cause a buildup of dense-core vesicles in this type of photoreceptor. If this is not the case then it at least raises the possibility that rods and cones have different neurotransmitters.

Tolerance of *Lolium* hybrids to quantitative variation in nuclear DNA

THE genus *Lolium* contains six species, all diploids with 14 chromosomes. The chromosomes of the inbreeding species are larger than those of the outbreeders and carry about 30% more DNA¹. Although the range of variation in nuclear DNA amount is not large, in comparison with other genera of flowering plants², *Lolium* is exceptional in that crosses between diploid species with widely different amounts of DNA produce F₁ hybrids which set viable seed on backcrossing or, alternatively, by intercrossing to produce F₂s. Segregation of nuclear DNA amount among hybrid derivatives by independent chromosome assortment and crossing over at meiosis in the

F₁ makes feasible a genetic assay of the effects of the differential interspecific DNA component. This report describes the segregation of nuclear DNA amounts among F₂ progenies (seedlings 5–7 d old) from F₂ hybrids between *L. temulentum* with high DNA and *L. rigidum* with low DNA content. F₁ seeds were obtained by allowing the F₁ hybrids to intercross in isolation from foreign pollen. From the DNA distribution in F₂ it is possible to draw conclusions about the influence of the differential DNA component on gamete and zygote viability. The results are given in Fig. 1.

As the result of recombination in F₁, DNA values range from approximately that of the low DNA parent to the high. Moreover, the distribution closely approaches and does not differ significantly from that of a normal curve. We conclude, in respect of the viability of gametes and of zygotes, toleration of a wide range of DNA amounts. Comparable quantitative DNA variation brought about by aneuploidy, that is by gain or loss of whole chromosomes, in *Lolium*⁴ as in most eukaryotes is the cause of severe genetic imbalance causing high mortality. We infer, therefore, that the 30% fraction of the DNA that distinguishes *L. temulentum* from *L. rigidum* is, genetically, of a substantially different character from that representative of whole chromosomes. Biochemical analyses in *Plethodon*⁵ have confirmed an earlier prediction⁶ that quantitative DNA

differences between related species involve mainly a particular and distinctive fraction of the nuclear DNA. The molecular distinctiveness finds a parallel in terms of genetic activity.

Growth and development of F₂ plants are normal in the sense that the variation in leaf production, shoot growth and flowering time lies within the range displayed by the parents. This is not to say, however, that the extra DNA in *L. temulentum* may be considered strictly inert. In this connection it will be observed that the mean nuclear DNA content of the F₂ progenies (23.6) is significantly lower ($P < 0.01$) than that of the mid-parent (F₁) value, 26.1. A possible explanation is that the development and viability of gametes or zygotes carrying mainly *L. temulentum* type chromosomes are at least partly dependent on the differential DNA fraction. Whether this interpretation is justified awaits additional evidence from more detailed assays.

The distribution of DNA amounts among the backcross progenies of *L. perenne* × *L. temulentum* given by Rees and Jones¹ leads to the same conclusions as those reported here. Above all, the evidence establishes, on a genetic rather than a biochemical basis, that the large scale variation in nuclear DNA amount among these eukaryote species involves a distinctive DNA component, distinguished by its relative inertness in comparison with that representative of whole chromosomes. In this respect there is an analogy with the DNA contributed by supernumerary B chromosomes⁵. Finally, since gametes and zygotes are tolerant of a considerable variation with respect to this nuclear DNA fraction it is the more surprising that the nuclear DNA amount within species of eukaryotes is so constant. The question arises as to whether the main restriction on quantitative change may, after all, lie more with the initiation of such change than with its consequences.

We thank Mr Ian Taylor and Dr G. M. Evans for F₂ seeds and Dr A. Durrant for calculating the normal curve in Fig. 1.

Fig. 1 Nuclear DNA amounts (in arbitrary units) at G1 in *L. rigidum*, in *L. temulentum* and in 48 F₂ seedlings. Measurements were made on a microdensitometer (Vickers M85). Feulgen-stained root meristems were prepared by the method of McLeish and Sunderland³. Seedlings were handled in six batches of eight. A control (*L. temulentum*) was scored with each batch and adjustments were made to correct for minor fluctuations in readings between batches of slides. The theoretical normal curve is superimposed on the F₂ histogram.

Similarities and differences in latitudinal adaptation of two *Drosophila* sibling species

THE *melanogaster* subgroup in the *Drosophila* genus now includes six different species: four of them are found in tropical countries of the Ethiopian biogeographic region (*D. yakuba* Burla, *D. teissieri* Tsacas, *D. erecta* Tsacas and Lachaise, *D. mauritiana* Tsacas and David) whereas the two better known species, *D. melanogaster* and *D. simulans*, are widespread cosmopolitans. This geographical distribution is a strong argument for a tropical African origin of the subgroup¹ and it suggests that genetically only two species were sufficiently versatile for adaptation to northern and southern temperate climates.

Ecological observations, indicating that the two cosmopolitan species are linked to human activities², suggest that the species have been distributed by man during historical time; that they occupy similar ecological niches which are fairly constant all over the world; and that human transportation mixes the flies, resulting in a uniform genotypical composition throughout the range. Evidence is accumulating, however, that such suggestions may be incorrect and, consequently, that cosmopolitan species are indeed interesting for evolutionary studies³.

In *D. melanogaster*, linear latitudinal clines have been demonstrated for two quantitative polygenic traits (adult weight and female ovariole number) among temperate strains from Europe and North America, and tropical strains from equatorial Africa and America⁴. Preliminary studies suggested a similar phenomenon in *D. simulans*⁵. We have therefore undertaken a more extensive analysis. Results for 32 different strains of *D. simulans* (Fig. 1) are compared with the *D. melanogaster* data.

D. simulans is lighter and has fewer ovarioles than *D. melanogaster*; otherwise they are fairly similar. The fresh weight of females increases linearly with latitude and the slopes for the two species are otherwise not significantly different (the results for males (not shown) point to the same conclusion). For ovariole number, the increase for *D. simulans* falls off above 20° or below -20° latitude. From 0 to 20° the slope is significantly higher than from 20 to 45°. But these slopes are not significantly different from the single regression calculated for *D. melanogaster*.

As emphasised previously⁴ the adaptive significance of ovariole number and body weight must be explained by physiological traits such as reproductive capacity and resistance to environmental stress. Thus we decided to study another purely physiological trait, ethanol tolerance, the importance of which, in the ecology of the two species, has been discovered⁶. The variation of lethal concentration for adults as a function of

Fig. 1 Regression of female fresh weight and ovariole number on the latitude of origin of *D. melanogaster* and *D. simulans* strains. All measures were made on flies raised in standard laboratory conditions (25°C; killed yeast rearing medium; low larval density). For *melanogaster*, only the average points (■) of groups of strains are shown (see ref. 4). For *D. simulans*, each point corresponds to one strain: x, American strains; ●, European or African strains. Regression parameters for *D. simulans* (r , coefficient of correlation; b , slope; n , number of strains): Female weight: $r = 0.69$, $b = 0.315 \pm 0.059$, $n = 32$; ovariole number, below 20°: $r = 0.91$, $b = 0.293 \pm 0.033$, $n = 17$; 20–50°: $r = 0.51$, $b = 0.080 \pm 0.028$, $n = 24$. In *D. melanogaster*, regression parameters for 51 strains: female weight: $r = 0.93$, $b = 0.503 \pm 0.029$, ovariole number: $r = 0.77$, $b = 0.179 \pm 0.021$.

Fig. 2 Variation of ethanol tolerance in relation to the latitude of origin of the strains: ■, *D. melanogaster*, ●, *D. simulans*. Regression parameters (r , coefficient of correlation; b , slope; a , intercept, n , number of strains): *D. melanogaster*: $r = 0.90$, $b = 0.200 \pm 0.021$, $a = 7.69 \pm 0.63$, $n = 22$; *D. simulans*: $r = -0.23$, $b = -0.005 \pm 0.008$, $a = 4.79 \pm 0.25$, $n = 10$.

latitude of origin is shown in Fig. 2 (see ref. 7 for methods). In *D. melanogaster*, ethanol tolerance increases greatly with latitude; in *D. simulans*, however, the alcohol tolerance is lower and independent of latitude.

The higher ethanol resistance of *melanogaster* explains why it is the only species able to grow in highly alcoholic substrates such as fermented grapes in wine cellars^{6,8}. It seems probable that the geographical extension of *D. melanogaster* towards temperate countries occurred with a modification of its ecological niche, the species gradually becoming more linked to human activities such as artificial fruit fermentations. Much attention has been paid to the activity of alcohol dehydrogenase (Adh), which metabolises ethanol⁹. It now seems that alcohol tolerance is related to Adh activity (refs 8, 9, and B. Clarke, A. Elens and J. McDonald, personal communications). It is also known that, between the two widespread *Adh* alleles (slow and fast), fast usually shows a higher enzymatic activity¹⁰. Finally, a latitudinal cline (increase of fast frequency with latitude) has been demonstrated in the North American continent^{10,11}. All these data agree with the idea that the cline for alcohol tolerance described here corresponds, at a genetic level, to an increase of the fast allele frequency in temperate countries. Laboratory studies have demonstrated the selective value of the *Adh* alleles in experimental conditions^{9,12} and data from wild populations seem to demonstrate their selective values in nature.

The case of *D. simulans* is quite different, as the latitudinal adaptations seems to be independent of alcoholic food sources. This suggests that *D. simulans* may be less linked to (at least certain) human activities than *D. melanogaster*.

Latitudinal clines, on a shorter scale, have been demonstrated for biometrical polygenic traits in other (non-domestic) *Drosophila* species^{13,14}. The occurrence of similar data in two domestic species suggests that the natural selective mechanisms were the same—probably an adaptation to the average temperatures of the different regions.

An important problem is the time needed for the development of these genetic adaptations. Laboratory experiments indicate that less than 25 generations of artificial directional selection on equatorial strains are required to reach the higher weight, or higher ovariole number, of temperate strains. Moreover, experiments in population cages at different temperatures

have shown that biometrical characters of *D. pseudoobscura* can change significantly within a few years¹⁵. For *D. melanogaster* and *D. simulans*, the time needed for the genetic transformations induced by climatic changes is still a matter of debate. It may be that many thousands of generations were necessary for the fly populations to adapt from tropical to temperate conditions. Other species of the *melanogaster* subgroup and certain widespread domestic species such as *D. ananassae* have demonstrated an incapacity to extend their geographical distribution. We cannot, however, eliminate the commonly assumed possibility that the geographical extension of *D. melanogaster* and *D. simulans* is a recent event and that the colonisation of new regions was mediated by human transportations.

If this was indeed the case, a new question arises: why are so many tropical species, repeatedly introduced into temperate countries (for example, by escaping from laboratories) unable to found colonies? An answer may be found in the peculiarities of the genome of the cosmopolitan species. The study of allozymes, however, has failed to show systematic differences in level of polymorphism between cosmopolitan and other wild species¹⁶. Important differences exist in the chromosomal polymorphism of *D. melanogaster* and *D. simulans*: the former is highly polymorphic all over the world whereas the latter is monomorphic¹⁷. Such differences, however, seem to be of little importance for the adaptive capacities of the species.

Many problems thus remain in understanding the ecological genetics and the evolutionary capacities of the best known *Drosophila* species. A controversy has arisen over whether electrophoretic protein variants are "neutral" or "selective"¹⁸. Our data support a belief in the adaptive value of *Adh* alleles in nature. They also draw attention to the adaptive significance of biometrical polygenic systems which have often been neglected in current theories.

We thank B. Clarke and R. Grantham for help with the manuscript, and M. F. Arens, M. De Scheemaker-Louis and P. Fouillet for assistance.

Influence of selection pressures on enzyme polymorphisms in *Drosophila*

KIMURA^{1,2} suggested that the widespread enzyme polymorphisms revealed by electrophoresis in *Drosophila*, man and other outbreeding species are due to the selective neutrality, or near-neutrality, of most mutations. Others have argued that the observed genetic variation is adaptive, since electrophoretic variants may differ in their biochemical properties³, different classes of enzymes show conspicuously different levels of heterozygosity⁴⁻⁶, and natural selection in the laboratory may lead to detectable gene frequency changes at enzyme loci⁷.

Yamazaki and Maruyama^{8,9} concluded, from a survey of observed gene frequencies at 1,045 protein loci in a wide variety of species, that the data are compatible with the hypothesis of strict neutrality. A similar analysis¹⁰ of the data for three *Drosophila* species, however, has shown a significant excess of alleles with mean frequencies less than 0.1, by comparison with expectations based on the neutral infinite allele model of Crow and Kimura¹¹, presumably due to the accumulation of mutant alleles of minor deleterious effects¹².

In this report, a more extensive set of gene frequency data from electrophoretic surveys of species of *Drosophila* is analysed to assess the average magnitude of the selection pressures involved. The data are derived from 12 large scale studies of nine species of *Drosophila*¹³⁻²². The analysis involves only those enzymes for which at least three localities were sampled, and only those alleles reaching a frequency of 0.01 or more in at least one locality¹⁰.

Fig. 1 The relative contribution of five gene frequency classes to heterozygosity for group I enzymes in *Drosophila* (▲), compared with expectations for the neutral charge class model (●) at equilibrium with $N\mu = 0.08$, determined by computer simulation.

Two types of genetic model have been used for comparison with the *Drosophila* data. The infinite allele model assumes that mutation to novel and individually distinguishable alleles occurs with frequency μ per generation. The charge class model, introduced by Ohta and Kimura²³, assumes that mutation occurs with frequency μ to novel alleles, of which a proportion α is not distinguishable electrophoretically from the parent allele, a proportion β gives rise to a protein differing by one unit of electric charge from the parental protein, and a proportion γ differs by two units of charge. Positive and negative changes in charge are assumed to be equally probable. Johnson²⁴ argued that the infinite allele and charge class models represent the two extremes of allelic non-identification when electrophoretic techniques are used.

The theoretical equilibrium gene frequency distribution in a random mating population of size N is known for the neutral infinite allele model²⁵, but not for the neutral charge class model. The equilibrium distribution for the charge class model has therefore been determined by computer simulation, using the values of $\alpha = 0.66$, $\beta = 0.32$, and $\gamma = 0.02$ calculated by Marshall and Brown²⁶ from the 'average protein' of King and Jukes²⁷, assuming that all mutations involve single random DNA base substitutions. The computer simulation was carried out with a population size of $N = 500$, allowing a period of

Table 1 Comparison of gene frequency distribution observed for group I enzymes in *Drosophila* and expected at equilibrium for genetic models involving slightly disadvantageous mutations ($Ns = 3$)

Genetic model	Relative contribution to heterozygosity of gene frequency class*					Mean heterozygosity
	1	2	3	4	5	
Infinite allele $N\mu = 0.14$	3.29 (± 0.11)	2.46 (± 0.06)	1.32 (± 0.04)	0.48 (± 0.04)	0.16 (± 0.05)	0.090 (± 0.002)
Charge class $N\mu = 0.40$	2.85 (± 0.14)	2.55 (± 0.09)	1.40 (± 0.04)	0.54 (± 0.03)	0.18 (± 0.04)	0.089 (± 0.003)
Group I enzymes	3.10 (± 0.45)	2.40 (± 0.38)	1.07 (± 0.22)	0.45 (± 0.12)	0.37 (± 0.14)	0.102 (± 0.012)

*Corresponding to mean gene frequencies falling in the intervals (1) 0.001–0.050 or 0.950–0.999; (2) 0.051–0.100 or 0.901–0.950; (3) 0.101–0.200 or 0.801–0.900; (4) 0.201–0.300 or 0.701–0.800; and (5) 0.301–0.700. s.e. of estimation is given in parentheses.

20N generations for the attainment of a stationary gene frequency distribution. Thereafter, the gene frequencies in every generation for all electrophoretically distinguishable variants were tabulated over a period of 200N generations. The standard errors associated with the frequency distribution and mean level of heterozygosity were estimated from the observed variance among independent computer runs.

Figure 1 shows the gene frequency distribution for group I enzymes, that is, those which take part in glycolysis, the citric acid cycle or hexose monophosphate shunt, or whose substrates are in one of these pathways²⁸, compared with that for neutral alleles using the charge class model with the same overall level of heterozygosity. The ordinate in each case is the relative contribution of each gene frequency class to the total frequency of heterozygotes^{8,10}. For each of the 12 *Drosophila* surveys the contribution of a gene frequency class to heterozygosity has been expressed as a proportion of the total frequency of heterozygotes, and the relative contributions averaged over species with weights proportional to the number of independent alleles involved¹⁰.

The departure of the *Drosophila* group I enzyme data from expectations based on the neutral charge class model is statistically highly significant: the same applies to the neutral infinite allele model²⁸. There is a marked excess of alleles with mean gene frequencies in the range 0.0–0.1 or 0.9–1.0, and a corresponding deficiency in the range 0.2–0.8 (Fig. 1).

To simulate the *Drosophila* group I enzyme data, it is only necessary to suppose that all mutations are very slightly disadvantageous. Table 1 shows the results of simulation of an infinite allele model and a charge class model in which each mutant has a selective disadvantage s as a heterozygote, compared with the homozygote for the allele from which it arose, with all genotypic fitness values being determined additively. This model has been analysed deterministically by King and Ohta³⁰. In the charge class model, relative electrophoretic mobility is determined by differences in electric charge alone, but reproductive fitness does not depend on the net charge of the protein molecule. A charge class may contain two or more alleles with different selective values. Table 1 shows that selective pressures corresponding to $Ns = 3$ are sufficient to account for the observed departure of the group I enzyme data from the neutral hypothesis.

The gene frequency distribution for group II enzymes, that is, those not involved in glucose metabolism, is shown in Fig. 2. The corresponding neutral charge class model with an equivalent mean level of heterozygosity is given for comparison. The excess of alleles at extreme frequencies is not as marked as for group I enzymes, but it is, nevertheless, statistically highly significant: the same is true of the neutral infinite allele model²⁸.

**Fig. 2** *Drosophila* group II enzyme loci (Δ) compared with expectations for the neutral charge class model (\bullet) with $N\mu = 0.25$.

Table 2 shows that the models of mutation to slightly deleterious alleles with additive genotypic fitness values give equilibrium gene frequency distributions similar to that of group II enzyme loci when $Ns = 1$. The fit is not completely satisfactory, however, the data departing significantly from the model in

Table 2 Comparison of the gene frequency distribution observed for group II enzymes in *Drosophila* and expected at equilibrium for genetic models involving slightly disadvantageous mutations ($Ns = 1$)

Genetic model	Relative contribution to heterozygosity of gene frequency class					Mean heterozygosity
	1	2	3	4	5	
Infinite allele $N\mu = 0.14$	1.45 (± 0.09)	1.45 (± 0.08)	1.24 (± 0.04)	0.93 (± 0.02)	0.69* (± 0.06)	0.208 (± 0.012)
Charge class $N\mu = 0.40$	1.15 (± 0.08)	1.36 (± 0.08)	1.26 (± 0.04)	0.98† (± 0.02)	0.75† (± 0.05)	0.190 (± 0.010)
Group II enzymes	1.47 (± 0.17)	1.44 (± 0.10)	0.94 (± 0.14)	0.68 (± 0.12)	0.96 (± 0.08)	0.226 (± 0.015)

*Significant departure from group II enzyme data at $P = 0.01$.

†Significant departure from group II enzyme data at $P = 0.05$. s.e. given in parentheses.

having an excess of allele frequencies in class 5, that is, in the range 0.3–0.7. Such an excess could be accounted for by two-allele polymorphisms at 5–10% of group II enzyme loci, maintained by balancing selection of sufficient intensity to keep gene frequencies in the range 0.3–0.7, with the remaining loci producing only deleterious mutants with N_s values of 2 or less²⁹. Among the group II enzymes, adenylate kinase, aldehyde oxidase and xanthine dehydrogenase contribute most to the excess of gene frequencies in the range 0.3–0.7.

It may therefore be concluded that the gene frequency data for group I and group II enzymes in *Drosophila* can be accounted for by mutation–selection balance at more than 95% of the loci concerned; and that the mean selection intensity influencing the deleterious mutant alleles at these loci is of an extremely low order, corresponding to N_s values in the range 1–3. Even if it were supposed that effective population size in species of *Drosophila* is as low as 1,000, the selective disadvantage of mutant heterozygotes implied by this analysis is of the order of 0.1–0.3%. Selection pressures of this magnitude are far too small to be detected experimentally³¹, and can only be revealed by extensive surveys of large numbers of enzyme loci.

Evidence for a malaria mitogen in human malaria

HYPERGAMMAGLOBULINAEMIA is a prominent feature of human malaria. Serum levels of IgM and IgG rise rapidly in acute infections¹, and malaria has been implicated as an important cause of the raised levels of these immunoglobulins and the increased prevalence of rheumatoid factor and other autoantibodies found in healthy subjects in many parts of the tropics. Only a small proportion of the immunoglobulin produced in malaria can be shown to be specific antibody². The mechanisms underlying the production of large amounts of nonspecific immunoglobulin in malaria have not been established. Excessive immunoglobulin production could result from a breakdown in normal control mechanisms, perhaps as a consequence of the deletion of suppressor T cells. Alternatively, it could be due to the production during malarial

infection of a substance capable of stimulating lymphocytes nonspecifically³. Here we present evidence for the production of a mitogen in children with acute *Plasmodium falciparum* malaria.

Sera were obtained from 19 children with acute *P. falciparum* malaria at the time of presentation at hospital and from 16 healthy European adults taking regular malaria prophylactics. Blood for parasite culture was obtained from seven other children with acute *P. falciparum* malaria. None of these children had cerebral malaria or were clinically anaemic. Parasitaemia ranged from 1% to 15% parasitised erythrocytes with a mean of 7%. Blood for control cultures was obtained from six healthy Europeans who had never had malaria and who were taking regular malaria prophylactics. Heparinised blood, diluted 1.3 in RPMI 1640 medium, was passed through a column of CF 11 cellulose powder to remove white cells⁴. The diluted blood was washed through the column with RPMI 1640 and 5-ml samples collected. The first tube usually showed some haemolysis and was discarded. The next five or six tubes, containing only an occasional white cell, were collected and pooled. The red cells obtained were washed twice in fresh medium and a culture mixture was prepared containing 2 volumes of packed red cells, 2 volumes of inactivated foetal calf serum (FCS) or horse serum and 6 volumes of RPMI 1640. Culture was carried out in sterile conditions at 37 °C in 50-ml conical flasks loosely stoppered with cotton wool, in an atmosphere of 5% CO₂ in air.

After 24 h the culture was centrifuged and the supernatant retained. The remaining erythrocytes were washed twice in fresh medium, diluted 1.3 in RPMI 1640, layered over a Ficoll–Hypaque gradient and centrifuged at 400g for 30 min at 20 °C. This procedure removed remaining lymphocytes but resulted in the loss of some parasitised

Fig. 1 Mean stimulation ratio obtained on 3-d culture of lymphocytes from six immune Nigerians (●) and six non-immune Europeans (○) in the presence of different concentrations of supernatants obtained from culture of infected red cells. a, Supernatant 2; b, supernatant 3. Bars indicate the s.e.m.

Table 1 Stimulation ratios

	50%	Supernatants 10%	1%	10%	Red cell lysates 1%	0.1%
Malaria cultures	2.0 (0.5-9.2)	4.2 (0.9-17.4)	2.0 (1.0-6.0)	2.4 (0.4-9.0)	1.9 (0.8-3.4)	1.5 (0.5-2.1)
Control cultures	0.9 (0.3-1.4)	0.9 (0.7-1.1)	1.0 (0.9-1.1)	1.0 (0.8-1.2)	1.2 (0.9-1.9)	0.7 (0.3-1.5)

Mean stimulation ratios were obtained on 3-d culture of lymphocytes from two non-immune subjects in the presence of different concentrations of supernatants and red cell lysates prepared from seven infected and six control erythrocyte cultures. Figures in parentheses indicate the range of stimulation observed.

erythrocytes and free malaria parasites. The sedimented erythrocytes were washed twice in medium and lysed with 0.87% ammonium chloride buffered with Tris-HCl buffer. After further washing the deposit was disrupted by sonication. The resulting supernatant, described here as a red cell lysate, was sterilised by Millipore filtration and stored at -40°C until tested. Protein concentrations of red cell lysate preparations were in the range of $1.3\text{--}5.5\text{ mg ml}^{-1}$. Blood from control subjects was treated in an identical way to blood from patients with malaria.

Sera, culture supernatants and red cell lysate preparations were tested for mitogenic activity on human peripheral blood lymphocytes and on mouse spleen cells. Lymphocytes were cultured in RPMI 1640 plus 10% FCS in microtitre trays at a concentration of 1×10^6 lymphocytes per ml for human peripheral blood cells and at a concentration of 3×10^6 lymphocytes per ml for mouse spleen cells. Eighteen hours before collection $1\text{ }\mu\text{Ci}$ of ^3H -thymidine was added to each well. Cells were collected on glass fibre disks with a Millipore manifold. Stimulation ratios have been calculated as the c.p.m. given by the test sample minus background divided by the c.p.m. given by the control sample minus background. Control cultures contained the same concentration of FCS or horse serum as the test samples. In each assay lymphocytes were tested against PHA at a final concentration of $50\text{ }\mu\text{g ml}^{-1}$.

Lymphocytes from a healthy European were cultured for 3 d in 10% serum obtained from 19 children with acute malaria and in 10% serum obtained from 16 controls. Three malaria sera, but none of the control sera, gave a stimulation ratio greater than 2 but other sera from the children with malaria were toxic, resulting in low cell viabilities and low stimulation ratios. Thus the mean stimulation ratio obtained on culture of lymphocytes in sera from children with acute malaria (1.0 ± 0.8) did not differ from the mean ratio obtained on culture in control sera (1.0 ± 0.5).

Supernatant and red cell lysate preparations obtained from culture of infected and control erythrocytes were tested for ability to stimulate lymphocytes obtained from two Europeans not immune to malaria (Table 1). Five out of seven supernatants and three out of seven red cell lysate preparations obtained from cultures of infected erythrocytes gave a stimulation ratio of 2 or more whereas none of six control supernatants or red cell lysate preparations gave stimulation of this degree. The mean stimulation ratio obtained with phytohaemagglutinin was 48.5 ± 19.6 .

The two malaria supernatants and the two malaria red cell lysate preparations which gave the most marked stimulation in this initial experiment were tested for mitogenic activity on lymphocytes obtained from six adult Nigerians immune to malaria, on lymphocytes from six non-immune Europeans and on mouse spleen cells. Results for the two supernatants are shown in Fig. 1 and for the two red cell lysate preparations in Fig. 2. Although a wide range of responses was observed between different subjects each preparation gave a greater mean response in immune Nigerians than in non-immune Europeans. The different shapes of the dose-response curves obtained with supernatant 3 and red cell lysate 7 in immune and non-immune subjects also suggests increased sensitivity of lymphocytes

from immune Nigerians to these preparations. Lymphocytes from each subject responded to PHA with a mean stimulation ratio of 35.3 ± 19.7 for the European donors and a mean stimulation ratio of 12.3 ± 8.3 for the Nigerian donors. The low ratio obtained with lymphocytes from Nigerian donors reflects the high rate of isotope incorporation shown by their unstimulated cultures, a common finding in the local community. Mouse spleen cells showed a similar response to the two malaria supernatants and red cell lysate preparations as blood lymphocytes from non-immune Europeans.

A time-response curve was determined for supernatant 2 using lymphocytes from an immune and a non-immune donor. In each case maximal stimulation was observed around the third or fourth day of culture.

This study has shown that preparations obtained from short term culture of malaria-infected erythrocytes can stimulate lymphocytes from both immune and non-immune individuals. Leukocytes were removed from the culture preparations by an initial filtration through cellulose and by a subsequent Ficoll-Hypaque purification but the possibility that the stimulation observed in our experiments

Fig. 2 Mean stimulation ratios obtained on 3-d culture of lymphocytes from six immune Nigerians (●) and six non-immune Europeans (○) in the presence of different concentrations of red cell lysate preparations obtained from infected red cells. a, Lysate 2; b, lysate 7. Bars indicate the s.e.m.

was due to a mixed lymphocyte reaction, or even to a reaction to a red cell antigen, cannot be completely excluded. We believe this to be unlikely, however, for the following reasons. First, none of the control supernatants or red cell lysate preparations produced significant stimulation. Second, supernatants, presumably containing products released by parasite-lysed erythrocytes, produced more stimulation than cell-lysate preparations. The reverse situation would have been expected if a white cell or red cell antigen was involved. Finally, lymphocytes from those immune to malaria responded better than lymphocytes from non-immune subjects suggesting that the stimulatory factor was related to the presence of malarial products in the test preparations. It thus seems probable that the mitogenic factor demonstrated in our experiments was produced by malaria parasites or by parasitised red cells during the culture *in vitro*. Lymphocytes from malaria-immune Nigerians showed a greater response to the malaria culture preparations than lymphocytes from non-immunes, suggesting that these preparations contained both a malaria antigen capable of eliciting a specific cellular immune response by sensitised lymphocytes and a powerful nonspecific mitogen able to stimulate non-sensitised human peripheral blood lymphocytes and mouse spleen cells.

Our results thus agree with the finding that an antigen prepared by lysis of whole blood from monkeys infected with *P. falciparum* stimulated markedly lymphocytes from most subjects who had experienced malaria, and that at high antigen concentrations, lymphocytes from non-immune controls and even lymphocytes from cord blood responded⁶. These findings suggest this malaria preparation also contained both an antigen able to elicit a specific cell-mediated immune response to malaria and a nonspecific mitogen.

There is increasing evidence of the development of specific cell-mediated immunity during human malaria infection but it has yet to be established whether this has any protective role. It has been suggested that sensitised T lymphocytes function as helper cells, aiding the rapid production of antibody to newly arising antigenic variants⁶. Macrophage activation as a result of lymphokine production could also have a protective role by enhancing phagocytosis of parasitised erythrocytes.

The results of this study support the view that a mitogenic factor is produced during the course of human malaria infection but it has yet to be established whether it plays any part in the production of the hypergammaglobulinaemia characteristic of the infection. We are currently investigating whether it acts predominantly on B lymphocytes or T lymphocytes and whether it can stimulate immunoglobulin synthesis by lymphocytes *in vitro*.

Lymphocyte activation *in vitro* to murine onco-foetal antigens

ONCO-FOETAL antigens (OFAs) are operationally defined as immunogenic cell surface components present on various types of malignant and foetal cells, but not present on adult cells^{1,2}.

As OFAs also seem to be shed from cell surfaces into blood and other body fluids, there is particular interest in the possible diagnostic value of detection of OFAs such as carcinoembryonic antigen^{1,2} and α foetoprotein³. In spite of many studies in this latter area, there is little information on either the basic function of OFA components or of their possible role in immune responses to tumours *in vivo*. Their frequent association with rapidly dividing cell populations suggests a role related to growth and differentiation rather than in the neoplastic process itself. Embryonic exposure of the normal individual to OFAs may induce immunological tolerance to these antigens, thus effectively negating any subsequent potential role of OFAs to act as tumour-associated transplantation antigens capable of eliciting an anti-tumour response *in vivo* in the host².

Fig. 1 Specific lysis of ⁵¹Cr-labelled target tumour cells by cytotoxic lymphocytes activated *in vitro* by syngeneic 14-d foetal liver cells, at a responder-stimulator ratio of 10:1. Cytotoxic lymphocytes were collected at indicated times (d) after initiation of culture, then held for 24 h in fresh medium before assay with ⁵¹Cr labelled MPC-11 cells (●, ○) or Wehi-164 cells (×). (CL-target ratio 100:1). Error bars are standard errors of triplicates.

For detailed investigations of this situation, animal models of OFAs are particularly appropriate, and various reports of OFAs on animal tumours have appeared^{2,4-6}. These include inhibition of chemical or viral carcinogenesis or suppression of tumour growth by foetal tissue immunisation, and in the reverse direction, inhibition of foetal cell proliferation by immunisation with tumour cells⁴⁻⁷. Analysis of the cellular mechanisms of immune responses to OFA in these situations has been limited, with one report demonstrating the presence of cytotoxic lymphocytes in the spleens of mice immunised with foetal cells, capable of lysing ⁵¹Cr-labelled tumour cells⁸. Analysis of the cellular components involved in anti-tumour responses has been aided by the development of totally *in vitro* systems for the induction and assay of anti-tumour immunity⁹⁻¹¹, making possible the control of variables which are difficult to evaluate *in vivo*. We now describe the *in vitro*

generation of cytotoxic lymphocytes by syngeneic foetal liver cells, and their ability to lyse syngeneic tumour cells.

The choice of foetal liver^{6,7} and the tumours used in this study was based on the results of investigations *in vivo*, demonstrating the ability of each tissue to provoke immune responses against the other (S.C., Wallis, and N.L.W., unpublished). The *in vitro* techniques used are described in detail elsewhere¹¹, and were briefly as follows. In all cases the microculture system of 4-ml compartments containing 15×10^6 responder cells was used. Irradiated (5,000 rad) BALB/c 14-d gestation foetal liver cells (stimulator cells) were cultured with 7-week-old male BALB/c spleen cells (responder cells) in Eagle's MEM containing non-essential amino acids, 5% foetal calf serum (FCS), and 10^{-4} M 2-mercaptoethanol at 37 °C in 10% CO₂ in air, using various ratios of stimulator-responder cells. At various times after initiation of culture, cells were collected and resuspended in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% FCS for a further 24 h before assay. On the day of assay, tumour target cells were labelled with ⁵¹Cr in DMEM and mixed with the cultured lymphocytes at a cytotoxic lymphocyte (CL) to target (T) ratio of 100:1 and 50:1. After incubation at 37 °C for 4 h and 45 °C for 1 h, the amount of ⁵¹Cr released to the supernatant was measured. Background (BG) lysis was determined by measuring the amount of ⁵¹Cr released without CL, and the total amount of releasable ⁵¹Cr (maximal count) (MC) was determined by adding Zaponin (improved lysing agent for white blood cell counts). The percentage specific lysis is $[(\text{test count} - \text{BG}) / (\text{MC} - \text{BG})] \times 100$. The tumour lines used were a methylcholanthrene-induced BALB/c fibrosarcoma¹² WEHI-164, and a BALB/c plasmacytoma, MPC-11, (provided by Dr M. Scharff, Albert Einstein College of Medicine, New York). In several studies, inhibition of specific lysis was attempted by adding unlabelled foetal liver, adult spleen or tumour cells at various ratios to the ⁵¹Cr target tumour cells during the assay phase.

The generation of CL induced by syngeneic foetal liver cells and capable of lysing syngeneic tumour cells is demonstrated in Fig. 1. Culture of cells for 4 d before the preincubation and lysis assay resulted in optimal specific lysis of either tumour. In comparison the percentage specific lysis of tumour targets using BALB/c lymphocytes cultured with irradiated adult BALB/c spleen cells averaged $9 \pm 2\%$, regardless of assay day. Although there was some variation in the degree of lysis of the target cells from one experiment to another there was always at least a threefold increase of ⁵¹Cr release with BALB/c anti-foetal liver compared with anti-adult spleen. As other studies^{13,14} have inferred the *in vitro* generation of self-reactive CL, it is essential to make this comparison of adult with foetal stimulator cells in these studies. Our data on specific lysis with anti-self-reactive cells and the inhibition data below, do not suggest that the reactivity observed against foetal liver and tumour cells is of this auto-reactive nature.

Varying the ratio of responder to stimulator cells revealed optimal lysis at 10:1 with both tumour targets, whereas, in studies with specific anti-tumour immune responses, optimal ratios were 100:1 for MPC-11 (ref. 11), and 1,000:1 for WEHI-164 (R.B. and N.L.W., unpublished), again stressing the different type of antigenic system involved in the OFA study. Preliminary studies have also indicated that the gestational age of foetal liver effects the level of specific lysis generated, with a progressive decrease from 13 to 16 d of foetal age.

Evidence for specificity of cytotoxic lymphocyte activation comes from blocking experiments using non-labelled cells. Specific lysis of ⁵¹Cr target tumour cells by cytotoxic lymphocytes could be inhibited quantitatively by addition of foetal liver cells or Wehi-164 cells during the assay (Fig. 2), whereas there was little effect with adult spleen cells. In such experiments we consistently observed marked inhibition with Wehi-164 cells, but considerably less with MPC-11 cells, possibly indicating quantitative differences in the expression of OFA on different tumours. The degree of inhibition with foetal liver cells has been at least three times greater than that observed with adult

Fig. 2 Inhibition of ⁵¹Cr release from labelled Wehi-164 cells (CL-target ratio 50:1) by unlabelled Wehi-164 (a), 14-d foetal liver (b) and adult spleen cells (c) at various ratios of blocking cells to labelled target cells. The error bars represent standard errors of triplicate assays.

spleen cells, particularly at high blocking ratios. Whether the requirement for a relatively large number of foetal liver cells as either stimulators or blockers of CL reflects the expression of OFA on only subpopulations of foetal liver cells (for example, haematopoietic stem cells^{6,7}) or low amounts on most cells, remains to be elucidated. Preliminary studies have suggested the presence of OFA in foetal tissues other than liver. When degrees of blocking obtained with foetal or tumour cells are compared, it should be noted that the tumour cells used are of considerably larger volume.

The data presented here are consistent with the thesis that murine foetal cells have antigens in common with several murine tumour cells, which are not present on adult normal cells. The ability to generate *in vitro* cytotoxic lymphocytes to these antigens now permits further analysis of the tumour-host relationship involving OFA. As the two tumours used in this study do not apparently share *in vivo* tumour-associated transplantation antigens, and yet do share OFA, we are now determining whether the *in vitro* expression of CL represents T cell or B cell-mediated responses, perhaps released *in vitro* from a persistent *in vivo* suppression mechanism, as proposed for the *in vitro* generation of autoreactivity¹³.

Altered serological and cellular reactivity to H-2 antigens after target cell infection with vaccinia virus

Mice generate cytotoxic T lymphocytes (CTL) which are able to lyse virus infected target cells *in vitro* after infection with lymphocytic choriomeningitis virus (LCMV) and pox-viruses¹⁻³. CTL kill syngeneic and semiallogenic infected cells but not allogenic infected targets. Target cell lysis in these systems seems to be restricted by H-2 antigens, especially by the K or D end of the major histocompatibility complex (MHC). In experiments where virus specific sensitised lymphocytes kill virus infected allogenic target cells⁴ the effector lymphocytes have not been characterised exactly. Recent investigations suggest that the active cell in this assay, at least in the measles infection, is a non-thymus derived cell (H. Kreth, personal communication). An H-2 restriction of cell mediated cytotoxicity (CMC) to trinitrophenol (TNP)-modified lymphocytes has also been described⁵. Zinkernagel and Doherty⁶ postulated that the CTL is directed against syngeneic H-2 antigens and viral antigens and they suggested an alteration of H-2 induced by the LCMV infection. Earlier⁷ we found a close topological relationship between H-2 antigens and the target antigen(s) responsible for CMC in the vaccinia system. Here we report experiments which were carried out to prove alteration of H-2 after infection of L-929 fibroblasts with vaccinia virus.

Alteration of H-2 antigens was studied by immunofluorescence. L-929 cells after 1 h infection with 10 TCID₅₀ per cell vaccinia virus strain WR and 19 h incubation in serum-free medium, as well as normal L-929 cells were stained by indirect immunofluorescence. L cells (5 × 10⁶) were incubated in 100λ H-2^k (charge D 3b, raised in recipient-donor strains (C3H-H2^k × 129) anti-C3H; genotypes (K^dD^k × K^bD^b) anti-K^dD^k. This serum is cytotoxic for H-2 specificities 11, 23, 25, 52 and haemagglutinating for specificity 3, (ref. 8) for 30 min, 37 °C and 4 °C and after washing 3 times in PBS incubated in 100λ FITC-labelled rabbit anti-mouse IgG in the same conditions. After the cells were washed three times, viability was tested (> 90%) and slides were prepared without previous fixation of cells. All of the normal fibroblasts had a dense and regular fluorescence, whereas about 25% of the infected cells lacked H-2 fluorescence. The remaining 75% cells had an irregular and more coarse-grained staining.

Fig. 1 H-2^k alloantiserum absorption with normal and vaccinia infected L-929 cells. ●—●, cytotoxic activity of anti H-2^k serum (⁵¹Cr release) against C3H spleen lymphocytes. ○—○, cytotoxic activity of anti H-2^k serum after 30 min absorption at 37 °C with 1 × 10⁸ vaccinia virus infected L cells (20 h infected 10 TCID₅₀ per cell vaccinia strain WR). ●—●, cytotoxic activity of anti H-2^k serum after absorption with 1 × 10⁸ normal L-929 cells. Serum dilutions were performed in Eagle's MEM. Each point represents N = 4 values ± s.d. Differences are statistically significant (P < 0.001). Maximal ⁵¹Cr release by H-2^k alloantiserum before absorption was calculated as 100% cytotoxic activity (Antibody mediated ⁵¹Cr release ranged from 40–65% of total incorporated chromium). Controls included spontaneous lysis of targets alone, lysis in presence of complement alone, H-2 antibodies alone, normal mouse serum alone and normal mouse serum together with complement.

Absorption studies were performed to quantify the possible H-2 alteration seen in immunofluorescence. Different numbers of viable infected and non infected L-cells (2.5 × 10⁷–1 × 10⁸) were incubated with 0.5 ml anti-H-2^k serum for 30 min at 37 °C. After this, the cytotoxic titre of the absorbed serum was tested in the ⁵¹Cr-release assay using C3H spleen lymphocytes (H-2^k) as targets and guinea pig serum as complement source (Figs 1 and 2). Then the lysis of target cells was assayed by Trypan blue exclusion using rabbit complement. Both tests gave nearly the same results.

Serum D-3b was absorbed quantitatively five times, with comparable results. There was a constant reduction of H-2 alloantiserum absorbing capacity of L-929 cells infected with vaccinia virus (Fig. 1). Using 1.0 × 10⁸ normal cells for absorption we found no cytotoxicity in the ⁵¹Cr-release assay. The complete absorption was not simulated by anti-complementary activity of the H-2 serum since the absorbed serum showed no more H-2 fluorescence, and absorption with increasing amounts of normal L cells showed a stepwise decrease of cytolytic activity. Serum absorbed with the same amount of infected cells showed cytolytic activity up to a serum dilution of 1:128. After absorption with 2.5 × 10⁷ and 5 × 10⁷ cells the anti-H-2^k serum showed 20–40% more cytolytic activity when infected cells were used for absorption (Fig. 2).

Table 1 Blocking of CMC against target cells infected with vaccinia virus

Lymphocytes*	Target cell	Cr release†	Specific lysis‡
Normal DBA/2	L-929	20.1 ± 1.2	
Normal C3H	not infected	18.5 ± 0.7	
DBA/2 sensitised to H-2 ^k		64.4 ± 0.8	44.3§
C3H sensitised to vaccinia virus		19.4 ± 1.3	
Normal DBA/2	L-929	21.2 ± 0.9	
Normal C3H	vaccinia virus infected	23.4 ± 0.8	
DBA/2 sensitised to H-2 ^k		22.5 ± 0.7	
C3H sensitised to vaccinia virus		72.8 ± 1.4	49.4§

*Lymphocytes from a pool of six mice per group. Virus sensitisation was performed by intraperitoneal injection of 1 ml 1 × 10⁶ TCID₅₀ ml⁻¹ vaccinia virus six days previously. Sensitisation to H-2^k was achieved by intraperitoneal injection of 1 × 10⁸ C3H spleen lymphocytes 10 d previously. Killer-target cell ratio, 100:1.

†Mean of percentage ⁵¹Cr release ± s.e.m. of 5 wells per group.

‡Specific lysis (%) = (⁵¹Cr release (%) by sensitised lymphocytes) – (⁵¹Cr release (%) by normal lymphocytes).

§Differences are statistically significant (P < 0.001).

The influence of target-cell infection on CMC was tested. Since the effector phase of the allograft reaction, which is reflected *in vitro* by the CMC of allogenic cells, is directed mainly against serologically defined (SD) antigens¹⁰, modifications of these antigens should influence the degree of CMC. DBA/2 mice (genotype H-2^k) were sensitised to H-2^k by intraperitoneal injection of 1×10^8 spleen cells from C3H mice. Ten days later, the DBA/2 lymphocytes were collected and the cytolytic activity of the CTL tested against infected and non-infected L-929 target cells in a ⁵¹Cr-release assay³. Table 1 shows the results of an experiment representative of the four carried out. After incubation of the CTL sensitised to H-2^k with the normal L cells we found a specific release of 44.3% of the incorporated chromium. There was, however, no specific lysis of the allogenic target cells infected corresponding to the serum absorption assays with vaccinia virus. In the immunofluorescence control the target cells had vaccinia virus surface antigen fluorescence and altered H-2 fluorescence as described above. In spite of serologically demonstrable H-2 antigens, the CTL could not kill the infected allogenic cells. With syngeneic attacker cells sensitised to vaccinia virus we observed significant specific lysis of the infected target cells.

Fig. 2 Comparison of quantitative absorption by different numbers of vaccinia virus infected and normal L-929 cells. ●—●, H-2^k (0.5 ml) absorbed on 0.5×10^8 L cells; ○—○, 0.5×10^8 vaccinia virus infected L cells; ■—■, 0.25×10^8 L cells; □—□, 0.25×10^8 vaccinia virus infected L cells. Maximal ⁵¹Cr. release by H-2^k antiserum before absorption was calculated as 100% cytotoxic activity.

These data indicate that infection of L-929 fibroblasts with vaccinia virus may result in a reduction and an alteration of H-2 antigenic sites. It has been shown by serum absorption tests that tumour viruses can increase or diminish the level of H-2 specificities^{11,12}.

H-2 antigen expression is cell cycle dependent¹³ and possibly the quantitative alteration after vaccinia virus infection could be caused by a virus-induced nonspecific blocking of the metabolism of membrane proteins. Using enteroviruses as infective agents we were not able to find a reduced H-2 allo-anti-serum absorbing capacity or an inhibition of lysis of allogeneically infected cells in the CMC. Expression of viral surface antigens seems, therefore, to be a prerequisite for antigenic alteration. Rearrangement of H-2 antigen specificities¹⁴ accompanied by virus-induced inhibition of membrane fluidity does not seem to be a sufficient explanation for the inhibition of T-cell effector function, since antigenic recognition is possible after fixation of cells¹⁵.

If the expression of H-2 in infected and non-infected cells were identical by serological means and infection induces only quantitative differences of H-2 antigen expression, the cells should be lysable in the CMC against alloantigens¹⁶. There is, however, not only slight reduction, but complete blocking of CMC. This could mean that there is a virus-induced qualitative

change of H-2 antigenicity or a steric hindrance of the target antigen for the T cell sensitised to alloantigen. Different localisation of serologically and cellularly detectable antigenic sites on the same molecule could also explain the different results of antibody binding and allogenic CMC. The latter possibility is supported by the finding that CMC between cells identical in SD antigens and different only in H-2 allo-anti-serum absorbing capacity occurs¹⁷⁻¹⁸. Reduction of CMC against allogenic cells has been obtained by Gardner *et al.*²⁰ in the ectomelia system while modification of cells with TNP did not alter CMC to H-2 alloantigens⁵. These contradictory results may reflect the different sizes of the modifying agents or the different process and extent of alteration.

Modulation of macrophage Fc receptor expression *in vitro* by insulin and cyclic nucleotides

THE capacity of certain cells to bind antibody or immune complexes through receptors at the cell surface may be important in both inductive and effector limbs of the immune response. Macrophages¹, B lymphocytes², activated T lymphocytes³ and certain tumour cells⁴ express such receptors which interact with the Fc portion of IgG (Fc receptors). I have shown that guinea pig macrophages are heterogeneous in their capacity to bind antibody, that the expression of Fc receptors is greatly increased during cell activation *in vivo* and *in vitro* and that this activation of receptor expression is inhibited by a factor(s) present in fresh autologous serum⁵. Here I show that changes in macrophage Fc receptor expression *in vitro* are modulated by insulin and by cyclic nucleotides.

Normal peritoneal cells were extracted aseptically from untreated outbred guinea pigs by washing the peritoneal cavity with 25 ml of RMPI 1640 tissue culture medium supplemented with 10% foetal calf serum (FCS) and containing heparin (5 U ml^{-1}). Samples (1 ml) of this suspension, which contained approximately 1×10^6 macrophages per ml, were placed immediately in each chamber of dual tissue culture slides (Lab-Tek Products). Cells from more than one animal were never pooled. These cells were incubated at

Fig. 1 The data are normalised by taking the percentage rosette formation in cultures exposed to insulin at 50 µg ml⁻¹ (△) as a reference and plotting the difference between these values and values in control cultures (○) and cultures exposed to insulin at 10 µg ml⁻¹ (▼). Each point represents the mean ± s.d. of three independent experiments.

37 °C for 2.5 h after which non-adherent cells were removed by washing the monolayer twice with heparin-free medium. The resultant monolayers, which consisted of macrophages of >95% purity, were cultured in RPMI 1640 supplemented with 20% FCS in an atmosphere of 5% CO₂ in air at 37 °C. In all cultures the medium was replaced every 24 h with a fresh preparation. Control cultures received RPMI with 20% FCS whereas experimental cultures received the same medium containing one of the following: insulin, dibutyryl cyclic AMP, dibutyryl cyclic GMP, 3-isobutyl-1-methyl-xanthine (IBMX), dibutyryl cyclic AMP+IBMX, dibutyryl cyclic GMP+IBMX, at the concentration specified.

Guinea pig IgG anti-sheep erythrocyte antibody was prepared from the sera of animals mounting a secondary response to sheep erythrocytes in Freund's complete adjuvant⁵. Antibody-sensitised sheep erythrocytes (EA) were prepared by incubating the cells with various concentrations of this antibody, and a degree of EA sensitisation appropriate for monitoring changes in macrophage Fc receptor activity was determined by obtaining a dose-response curve for rosette formation on monolayers at day 0 of culture, as described previously⁵. On subsequent days of culture the percentage rosette formation in control cultures in one chamber of a dual chamber slide was compared with that in experimental cultures in the other chamber. Thus, after rosette formation with a single preparation of EA, cultures were washed three times in Hanks' balanced salt solution, fixed with 1% glutaraldehyde and stained with buffered Giemsa. Five hundred cells were counted per culture and macrophages bearing five or more erythrocytes were scored as rosettes and expressed as a percentage of the total cells.

In control cultures the percentage rosette formation increased markedly as expected during 72 h of culture. When cells were cultured in medium containing 10 µg ml⁻¹ or 50 µg ml⁻¹ of insulin, however, the increase in receptor expression was inhibited to a degree related to the concentration of insulin present (Fig. 1). Existing Fc receptors were not blocked by insulin, but the increase in receptor expression was inhibited in a dose related manner. The effect therefore is unlikely to be due to steric hindrance of Fc receptors by surface-bound insulin. This *in vitro* effect resembles that of fresh autologous serum in that activation is inhibited⁶. Insulin did not significantly affect cell viability. When cells were cultured in the presence of dibutyryl cyclic AMP (5 × 10⁻⁵ M) the increase in receptor expression was again inhibited (Fig. 2). IBMX at the same concentration also inhibited the change in receptor expression. IBMX is a potent inhibitor of phosphodiesterases which hydrolyse cyclic AMP to form 5'-AMP (ref. 6); its presence should thereby cause an accumulation of intracellular cyclic AMP. When both dibutyryl cyclic AMP and IBMX were present the increase in receptor activity was inhibited to a greater degree than when either was present alone (Fig. 2). In the latter cultures Fc receptor activity remained at about the same level as that initially present. This synergistic effect would be expected to result from inhibition of the hydrolysis of both intracellular cyclic AMP

Fig. 2 The data are normalised by taking the percentage rosette formation in cultures exposed to 5 × 10⁻⁵ M dibutyryl cyclic AMP + 5 × 10⁻⁵ M IBMX (●) as a reference and plotting the difference between these values, control values (○), and values in cultures exposed to the following: dibutyryl cyclic AMP (△), dibutyryl cyclic GMP (□), IBMX (▼), dibutyryl cyclic GMP + IBMX (■) all at a concentration of 5 × 10⁻⁵ M. Each point represents the mean ± s.d. of four independent experiments. For clarity only one s.d. is shown on each point.

and dibutyryl cyclic AMP added to the medium. It further indicates that cyclic AMP, rather than 5'-AMP or other catabolites, exerts the observed effect. Dibutyryl cyclic MP (5×10^{-5} M) slightly augmented the increase in receptor expression (Fig. 2). When both dibutyryl cyclic GMP and IBMX were present at the same concentration the inhibitory effect of IBMX prevailed (Fig. 2). Presumably the effect of accumulated intracellular cyclic AMP is more telling than that of dibutyryl cyclic GMP added to the extracellular medium. Cell viability did not differ significantly between control and experimental cultures. Dibutyryl cyclic AMP at a concentration of 5×10^{-6} M had no effect on receptor expression (data not shown).

Cyclic nucleotides have been implicated in the control of various immunological and inflammatory functions⁷. In general cyclic AMP inhibits and cyclic GMP augments such functions as T-lymphocyte cytotoxicity⁸, lymphocyte proliferation and antibody production⁹, histamine release by mast cells¹⁰, lectin-induced uptake of calcium by T lymphocytes¹¹. My results are compatible with a model of macrophage activation in which the expression of Fc receptors is a function of antagonistic signals: insulin or hormones resembling insulin exerting a stabilising influence by maintaining a high intracellular cyclic AMP: cyclic GMP ratio, and other signals, possibly lymphokines, exerting an activating influence by lowering this ratio. The least requirement for activation *in vitro* may be the removal of the stabilising influence. It is interesting that a receptor for insulin has recently been demonstrated on human monocytes (R. H. Schwartz, A. R. Bianco, B. S. Handwerker, and C. R. Kahn, unpublished). A similar mechanism may also control T-lymphocyte Fc receptor expression which resembles that of macrophages⁵ in so far as the development of receptors during culture occurs in FCS but not in autologous serum¹². The expression of Fc receptors on cells derived from a murine myeloma has been shown to be inhibited by cholera exotoxin which increased intracellular cyclic AMP levels¹³.

An understanding of the mechanism controlling macrophage Fc receptor expression is important because changes in such expression may have a regulatory role both in the induction of an immune response and in the effector mechanisms of immunological surveillance. Increased receptor expression may facilitate the presentation of antigen to T lymphocytes since macrophage-bound antibody can mediate such presentation^{14,15}. It may also facilitate the killing of target cells by macrophages and I suggest that this explains the increased antibody dependent cytotoxicity exhibited by cultured macrophages¹⁶. Since circulating tumour antigen or antigen-antibody complexes seem to suppress the cellular response against tumours¹⁷, increased macrophage Fc receptor expression might also be expected to facilitate this response by accelerating the clearance of immune complexes.

I thank Drs A. S. Rosenthal and D. Linstead for discussion and Professor R. R. A. Coombs for his interest. I am supported by the Cancer Research Campaign and by a Beit Memorial Fellowship.

Molecular differences of exposed surface proteins on thrombasthenic platelet plasma membranes

THE platelet plasma membrane contains several proteins of different molecular weights. Three of these proteins stain for carbohydrate with periodic acid-Schiff reagent and have been termed glycoproteins I, II and III (molecular weights 150,000, 124,000 and 106,000, respectively)^{1,2}. It has been suggested that the bleeding tendency observed in Glanzmann's thrombasthenia results from abnormalities of the platelet membrane³⁻⁶. Nurden and Caen⁷ showed that glycoprotein II was absent in a crude membrane fraction isolated from thrombasthenic platelets. We have now investigated the surface composition of thrombasthenic membranes by the lactoperoxidase iodination technique² and found a low concentration of glycoprotein II, and other molecular differences.

When normal platelets are iodinated by the lactoperoxidase technique, glycoproteins I, II and III are labelled together with numerous other polypeptides of lower molecular weight². In addition a membrane component is labelled that has a molecular weight between that of glycoproteins I and II (refs 8 and 9). It is proposed that this component, which stained for carbohydrate, albeit poorly, be termed glycoprotein IIa while the former glycoprotein II be termed glycoprotein IIb. Figure 1 shows the iodination patterns from two normal donors.

The platelets from three patients⁸ fulfilling the diagnostic criteria of Glanzmann's thrombasthenia were iodinated with ¹²⁵I (CEA, Saclay, France), solubilised and mixed with solubilised normal platelets previously labelled with ¹³¹I. The mixtures were reduced with 2% 2-mercaptoethanol and submitted to sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis². The iodination patterns of the platelets from the three patients were almost identical and revealed marked differences from normal in the glycoprotein region. Figure 1a shows the iodination patterns obtained after coelectrophoresis of normal platelets with those from one of the patients. These patterns revealed an increase in the label associated with a polypeptide with an apparent molecular weight similar to glycoprotein I, a normal label associated with glycoprotein IIa and a decreased label associated with glycoproteins IIb and III. In addition, the molecular weight of thrombasthenic glycoprotein III was less than that of normal glycoprotein III. The ratio of the label associated with the glycoprotein region of thrombasthenic platelets from the three patients studied was 1.5:1.0:4.0:5, whereas that associated with the glycoproteins of normal platelets was 1:1:1:3.

The plasma membranes from iodinated thrombasthenic platelets were isolated by the glycerol-lysis technique¹². Thrombasthenic platelets lysed equally as well as normals and gave yields of plasma membranes within the normal range. Isolated membranes were then coelectrophoresed with normal iodinated platelets (Fig. 1b). A difference was observed between the iodination patterns of thrombasthenic platelets and isolated membranes from these platelets. Comparison of Fig. 1a and b shows that the labelled component of thrombasthenic platelets with an apparent mole-

Fig. 1 Comparison of the exposed polypeptides and glycoproteins of the plasma membranes of normal platelets and platelets from a patient with Glanzmann's thrombasthenia. Blood from a normal donor and the patient were anticoagulated using ACD (acid citrate dextrose)¹⁰ and the platelets were isolated and washed by the method of Massini and Lüscher¹¹. Washed normal platelets (1 ml, 10^9 platelets) were labelled with ^{131}I whereas the washed platelets from the patient (1 ml, 10^9 platelets) were labelled with ^{125}I by the lactoperoxidase technique⁹. Labelled platelets were washed twice and solubilised in 2–3% SDS. Labelled membranes from the patient's platelets were also isolated¹² and solubilised in 2–3% SDS. Samples labelled with ^{125}I were mixed with those labelled with ^{131}I . These mixtures were treated with 2% 2-mercaptoethanol, heated to 100 °C for 3 min, and submitted to electrophoresis on 5% polyacrylamide gels, sliced laterally into 1.6-mm disks and the radioactivity associated with each disk determined⁸. *a*, ^{125}I -labelled thrombasthenic platelets (●) and ^{131}I -labelled normal platelets (○); *b*, ^{131}I -labelled normal platelets (○) and plasma membranes from ^{125}I -labelled thrombasthenic platelets (●).

cular weight similar to that of glycoprotein I was not isolated with the plasma membranes. Further analysis revealed that this component was also not present in the residue fraction, but appeared in the supernatant. Normal glycoprotein I, however, is isolated with the plasma membrane fraction in a concentration similar to that present in whole platelets². It therefore seems that the labelled component in the glycoprotein I region of thrombasthenic platelets, which is absent on normal platelets, is not glycoprotein I but rather a component bound to the thrombasthenic membrane surface. The significance of the decreased label associated with thrombasthenic glycoprotein I is not clear since gels stained for carbohydrate of isolated thrombasthenic membranes (not shown) revealed that the concentration of glycoprotein I was within the normal range.

Another difference between normal and thrombasthenic platelets is the decreased iodination of glycoprotein IIb on the thrombasthenic platelet membrane. Nurden and Caen⁷ concluded from studies of gels of crude thrombasthenic membranes stained with periodic acid-Schiff that glycoprotein II (glycoprotein IIb) was absent. Staining of gels

for carbohydrate, however, cannot detect low concentrations of this component. In the study reported here, because of the greater sensitivity of the iodination technique, the amount of label associated with glycoprotein IIb was 40% of that present on the normal platelet membrane. We suggest therefore that the phenotypic expression of thrombasthenia is not an absence of glycoprotein IIb but rather a reduction in its concentration.

The study reported here demonstrates that glycoprotein III is also abnormal in Glanzmann's thrombasthenia. Nurden and Caen's results⁷ indicated that thrombasthenic glycoprotein III had a lower apparent molecular weight but that its concentration was similar to that of normal platelets. The data from the iodination experiments reveal that the decreased molecular weight of thrombasthenic glycoprotein III has drastically altered its expression on the membrane surface. The decreased iodination of thrombasthenic glycoprotein III may result from either an altered primary structure which could affect its orientation in the membrane or from a missing peptide containing a tyrosine residue which is iodinated in normal glycoprotein III. Since an additional component is found on the thrombasthenic platelet membrane surface it is possible that it sterically hinders the iodination of glycoprotein III.

Platelets from patients with Glanzmann's thrombasthenia do not aggregate to adenosine diphosphate (ADP), collagen or thrombin, even though collagen and thrombin induce thrombasthenic platelets to undergo a release reaction similar to normal platelets^{3–6}. Although ADP does not induce aggregation of these platelets, it does stimulate the platelet shape change⁴. Therefore, it seems that receptors for ADP, collagen and thrombin are present on the thrombasthenic platelet membrane but that these platelets lack an essential component necessary for normal aggregation. Since platelet aggregation involves interactions between membrane surfaces, the differences in the surface proteins of thrombasthenic platelets seen in our study could account for the absence of aggregation in this disorder and may indicate those components involved in normal ADP-induced aggregation.

Actin-tubulin homology revisited

THERE seems to be a principle underlying all eukaryotic motile systems. Movement, whether it be muscular, ciliar, flagellar or cytoplasmic, is apparently realised through the ATP-dependent sliding interaction of fibrillar proteins. This has raised the controversial question of whether the corresponding proteins from different systems are in fact homologues. Indeed, many proteins involved in motility have been isolated and characterised and have been reported as actins¹⁻⁵.

Evidence has been presented for^{6,7} and against^{8,9} the concept of homology between actin and tubulin, the monomeric unit of microtubules. (We use 'homology' in the sense defined by Stephens⁸.) Puszkín *et al.*^{10,11} demonstrated that colchicine-binding protein isolated from porcine brain¹⁰ and blood platelets¹¹ can stimulate ATPase activity of myosin in much the same way as actin. Others however, have shown large quantities of actin-like protein in these tissues^{12,13}, and so the results of Puszkín *et al.* might have been affected by contaminating actin.

The outer fibres of the ciliary axoneme provide an ideal tool for corroborating Puszkín and Berl's findings for large quantities of pure tubulin can be obtained easily⁶. There is no evidence that cytoplasmic actin is present in cilia of *Tetrahymena pyriformis*¹⁴.

Cilia of *T. pyriformis* (W strain) were isolated and purified as before⁶. Outer fibres were prepared by dialysing demembrated axonemes against a low ionic strength buffer (1 mM Tris-thioglycollate, 0.1 mM EDTA). The outer fibre fraction was dissolved in a solution containing the detergent Sarkosyl (0.5% Sarkosyl; 10 mM imidazole-HCl, pH 6.8; 100 mM KCl; 0.2 mM GTP and 0.1% mercaptoethanol) followed by Sephadex G-25 column chromatography to remove unbound detergent. The homogeneity of the preparation was determined by polyacrylamide gel electrophoresis¹⁵.

Chicken breast myosin was isolated by the method of Richards *et al.*¹⁶. The concentration of both tubulin and myosin was determined by the technique of Lowry *et al.*¹⁷, using bovine serum albumin as a standard. The ATPase activity of myosin, in both the presence and absence of outer fibre tubulin, was measured using the Fiske-Subba Row¹⁸ assay for inorganic phosphate (for details see Table 1).

The results are shown in Table 1 and Figs 1 and 2. Figure 1 illustrates the homogeneity of the preparation, for essentially only the two bands of A and B tubulin are present in the stained polyacrylamide gel. Table 1 summarises the effect of the addition of tubulin on the Mg²⁺ ATPase activity of myosin. Activity increased about 3.8 ± 0.4 times. The tubulin-myosin ratio was not critical; optimal stimulation of activity was at a ratio of 3:1 or greater. The trace amount of ATPase activity associated with the tubulin fraction probably represents residual dynein¹⁹.

The effect of changes in the pH of the reaction mixture

Fig. 1 Polyacrylamide gel electrophoresis of outer fibre tubulin from the cilia of *Tetrahymena*. The protein was reduced and alkylated as before⁶, and run in 5% acrylamide gels with 8 M urea¹⁵. Approximately 70 µg of protein were loaded per gel.

on the tubulin stimulation of myosin is illustrated in Fig. 2. The pH curve for the interaction shows an optimum at 6.0, decreasing sharply on either side (Fig. 2), thus emphasising the importance of pH in the tubulin-myosin interaction.

These results essentially agree with those of Puszkín *et al.*^{10,11}, but differ in one important aspect. They reported more than 20-fold stimulation of myosin activity with porcine brain¹⁰ and platelet¹¹ tubulin at pH 6.8 whereas we found a roughly two-fold stimulation at that pH (Fig. 2). An explanation for the lower stimulation may be a partial denaturation of the ciliary tubulin by Sarkosyl. Data indicate that muscle actin solubilised in Sarkosyl loses 70% of its ability to stimulate the ATPase activity of myosin

Fig. 2 Effect of pH on the stimulation of myosin ATPase by outer-fibre tubulin. The assay was performed as described in Table 1, except that the buffer used for pH values above 7 was Tris-HCl. Each point represents the average of at least two experiments. The degree of stimulation (DS) was calculated from the following formula: $DS = (MT - T)/M$ where M , T , and MT represent the specific activities of myosin, tubulin and myosin plus tubulin respectively. Note that a DS value of 1.0 represents no stimulation.

(unpublished work). On the other hand, a survey of the literature indicates that actin from different sources stimulates myosin ATPase activity to different degrees^{3,5}. If this is taken into consideration the value we obtained is comparable with that reported for the stimulation of muscle myosin by *Acanthamoeba* actin³ where the stimulation was approximately fourfold.

The optimal pH of the interaction (6.0) agrees rather well

Table 1 Stimulation of Mg²⁺ ATPase activity of muscle myosin by ciliary outer fibre tubulin.

Protein sample	Specific activity (µmol Pi per min per mg protein)
Myosin	0.028 ± 0.06
Tubulin	0.005 ± 0.01
Myosin and tubulin	0.097 ± 0.05

The reaction mixture consisted of 30 mM imidazole-HCl buffer, pH 6.0, at 25 °C; 0.06 M KCl; 0.5 mM ATP and 1 mM MgCl₂. Each tube contained 2 ml of reaction mixture plus 40 µg of myosin and/or 114 µg of tubulin. Duplicate samples were incubated in a water bath and stopped after 0 and 30 min incubation by the addition of 0.5 ml of sodium dodecyl sulphate, followed by 0.25 ml of molybdate reagent and 0.15 ml of the Fiske-Subba Row reagent. The tubes were then read at 660 nm with a Zeiss PMQ-11 spectrophotometer.

with the reported pK of histidine. This suggests that histidine and its methylated derivative in actin could play a role in the stimulation of the myosin ATPase activity by both actin and tubulin. This is supported by the finding that histidine is essential for the polymerisation of G-actin²⁰ together with the report that polymerisation is characteristic of the interaction between G-actin and myosin²¹.

The idea of homology between actin and tubulin arose from the finding that the amino acid composition and molecular weight of tubulin closely parallel those reported for actin⁶. Other workers questioned this homology. Mohri and Shimomura reported no stimulation of myosin by sea urchin sperm flagella⁹. However, they solubilised the tubulin in thermal conditions that could result in the denaturation of the protein²². Stephens⁸ bases his objections to the homology on the fact that the newer determination of the molecular weight of actin²³ does not agree with that established for tubulin. Indeed, he shows that the peptides produced by tryptic and chymotryptic digests of tubulin and actin isolated from *Pecten irradians* are dissimilar. There may however, be limited regions in the primary and tertiary structure of tubulin and actin that are similar, which could explain the stimulation of myosin by tubulin.

Cross innervation and the regulatory protein system of rabbit soleus muscle

SINCE Buller *et al.* demonstrated¹ that the contraction speed of skeletal muscle is determined by the nature of its innervation, there have been several reports that the biochemical composition and properties of muscle are likewise influenced. When the motor nerve to a slow muscle is replaced by a nerve that normally innervates a fast muscle, changes in phosphorylase, succinic dehydrogenase and myosin ATPase activities, such as would be expected if the biochemical characteristics of the fibres were changing from those of type I to those of type II, can be demonstrated histochemically². This is also true in the opposite situation, when the nerve to a fast muscle is replaced with one that normally innervates a slow muscle. The histochemical evidence implies that a change in concentration of the enzymes studied has occurred in response to the new type of innervation and although it would not be evident in such investigations, the possibility of change in isoenzyme complement cannot be excluded. In the case of myosin, however, which has been isolated after cross innervation, the changes

Fig. 1 Effect of cross innervation on the speed of contraction and the troponin I composition of rabbit soleus muscle. *a*, Electrophoresis of troponin I (20 μ g), isolated by affinity chromatography from rabbit soleus muscle (rabbit 2, see Table 1), in the presence of troponin C (50 μ g) from rabbit white skeletal muscle. 6 M urea, 25 mM Tris–80 mM glycine, pH 8.6, 8% acrylamide. O, Origin. i, Control soleus; ii, soleus from the other leg of the same animal 26 weeks after cross innervation. A, slow troponin I–troponin C complex; B, fast troponin I–troponin C complex; C, troponin C. *b*, Records of single isometric contractions of the soleus muscles used for troponin I preparations analysed in *a*. The distance between successive dots represents 10 ms. Vertical scale represents 100 g tension.

have been analysed with more precision. These indicate that when the contraction speed of skeletal muscle is altered by either cross innervation or long term electrical stimulation, there are changes in V_{max} of the myosin ATPase, in its light chain components and in its electrophoretic mobility^{3–7}. These changes imply that new myosin molecules of different primary and quaternary structure are being synthesised as a consequence of the altered activity pattern of the muscle resulting from these procedures. They correlate well with the widely accepted view that the V_{max} of the myosin ATPase rises with increasing muscle speed⁸ and the differences in light chain components known to exist in myosin from fast and slow skeletal muscle^{9–12}.

Biochemical investigations carried out so far on cross-innervated muscles have been restricted to enzymes involved in energy production and utilisation. As there is now good evidence that tropomyosin¹³ and the components of the troponin system differ in fast and slow skeletal muscle (see ref. 14 for review), we have investigated the effect of cross innervation on those proteins of the I filament which are involved in the regulation of the actomyosin ATPase.

Cross innervation of the soleus muscle was performed in 13 adult New Zealand Red rabbits under Nembutal anaesthesia. Using full aseptic precautions, the nerve to the soleus muscle in one leg was sectioned and sutured to the medial head of the gastrocnemius muscle to prevent self reinnervation. The nerve to the fast muscle, the lateral popliteal, was cut close to its point of entry in to the tibialis anterior muscle and sutured to the soleus. Between 2 and 6 months later, the soleus muscles of both operated and control legs were prepared for the recording of isometric tension¹⁵. Control muscles were stimulated by way of the cut peripheral end of the medial popliteal nerve with square-wave pulses of supramaximal intensity. Contractions of the cross-innervated muscles were elicited by stimulation of the lateral popliteal nerve. The medial popliteal nerve was also stimulated to assess whether some portion of the muscle had become self reinnervated. Times to peak tension of both muscles were measured from records of single twitches. When measurements were complete the muscles were frozen at -20°C and troponin I or tropomyosin subsequently isolated from both control and cross-innervated muscles.

For preparation of troponin I the muscles were homo-

Table 1 Effect of cross innervation on the relative proportions of the polymorphic forms of troponin I and tropomyosin in rabbit soleus muscle

Animal no.	Weeks after cross innervation	Cross innervated soleus					Control soleus			
		Contraction time (ms) X Own nerve	Contraction time (ms) nerve*	Tropomyosin α/β (molar ratio)	Troponin I		Contraction time (ms)	Tropomyosin α/β (molar ratio)	Troponin I	
					Fast (%)	Slow (%)			Fast (%)	Slow (%)
9	8	62	—	—	50	50	70	—	31	67
8	8	32	—	—	73	27	61	—	24	76

*The absence of figures in this column indicates that reinnervation by the muscle's own nerve did not occur.

Relative amounts of the fast and slow forms of troponin I and of the α and β subunits of tropomyosin were determined by comparing the intensities of staining with Coomassie brilliant blue of electrophoretic bands, using a Unicam SP500 spectrophotometer coupled to a Gilford linear transporter absorbance indicator. Electrophoresis of troponin I carried out in the conditions described in text and in Fig. 1; tropomyosin applied to a 10% (w/v) polyacrylamide gel with 0.1% SDS, 6 M urea, and 82.5 mM Tris-400 mM boric acid buffer, pH 7.0 (ref. 13).

genised in 20 vol of a solution containing 9 M urea, 1 mM CaCl_2 , 15 mM 2-mercaptoethanol, 75 mM Tris, adjusted to pH 8.0 with 1 M HCl, and applied to a Sepharose-troponin C affinity column as described¹⁰. After washing well with buffer and subsequent application of the same buffer in which the CaCl_2 was replaced by 10 mM EGTA, troponin I was eluted from the column free from other proteins.

Two polymorphic forms of troponin I are present in rabbit skeletal muscle. These are fast skeletal troponin I, which is the only form present in psoas and longissimus dorsi muscle¹⁰ and slow skeletal troponin I, which is the principal form present in red skeletal muscles such as the soleus and crureus. The two forms have different primary structures but migrate with identical mobilities on electrophoresis in SDS. Although neither form of troponin I migrates to the anode on electrophoresis in 6 M urea, 25 mM Tris-80 mM glycine, pH 8.6, the complexes formed by the two forms with troponin C in the presence of Ca^{2+} in these conditions show electrophoretic mobilities sufficiently different to allow them to be distinguished readily and their relative amounts estimated (Fig. 1). Control experiments using a sample of pure fast skeletal troponin I to which 3-4 times a molar excess of troponin C isolated from white rabbit skeletal muscle was added, showed that all the troponin I present in the mixture moved as the complex on electrophoresis in 6 M urea, pH 8.6. Thus by densitometric scanning of the bands of the complexes formed on electrophoresis when the total troponin I extracted from the muscle was mixed with excess troponin C, an estimate of the relative amounts of the two forms of troponin I present could be made. The validity of this procedure to within $\pm 3\%$ was confirmed by control experiments in which samples of troponin I of known composition were applied to the gel. In this way, we have shown that the troponin I of normal New Zealand Red rabbit soleus consists of about 30% fast and 70% slow skeletal troponin I.

In all cases in which the contractile speed of the soleus muscle increased after cross innervation, a corresponding change in the proportion of fast and slow troponin I was observed. On average, 22-27 weeks after cross innervation, the fast skeletal troponin I increased from 30% to more than 70% of the total troponin I extracted by affinity chromatography. In one experiment the troponin I present in the soleus was converted almost completely to the fast skeletal muscle type (Fig. 1 and Table 1, animal no. 2). Where physiological measurements showed that most of the muscle had become reinnervated by its own nerve (Table 1, animal no. 3), the speed of contraction remained slow

and there was no increase in the relative amount of fast troponin I. The change in the proportion of the two forms of troponin I seemed to precede the change in contractile speed in one animal (Table 1, animal no. 9) that was examined 8 weeks after the operation. This observation is being investigated further.

The form of troponin I that increased in amount was not a simple modification of the slow muscle type but represented new protein synthesis for the electrophoretic pattern of the cyanogen bromide digest was similar to that previously described for fast skeletal muscle troponin I of the rabbit and different from that of the cyanogen bromide digest of slow skeletal troponin I (ref. 16).

Tropomyosin was isolated from soleus muscles frozen immediately after measurement of the speed of contraction by the method of Cummins and Perry¹³. The protein was separated into the α and β components by electrophoresis, the bands stained with Coomassie brilliant blue and the relative amounts present determined by densitometric scanning¹³. A molar ratio of α and β subunits in soleus muscle of the New Zealand Red rabbit of 1.01 was obtained, which is similar to that reported for the New Zealand White rabbit¹³. The ratio did not change significantly 3-6 months after cross innervation, when the contraction time had increased by a factor of approximately two and marked changes in the troponin I composition had occurred (Table 1).

The evidence indicates that when the contractile speed of soleus muscle is increased by replacing its normal nerve supply by a nerve that usually supplies a fast muscle, the slow skeletal troponin I (which is the major polymorphic form of the protein present in whole soleus muscle) is replaced by fast skeletal muscle troponin I. If no changes in the relative rates of catabolism of these two proteins occur this implies that the change in innervation has altered the relative rates of synthesis of the two forms of troponin I, which, from their primary structural differences¹⁶, would be presumed to be under different genetic control.

Although the molar ratios of α and β subunits of tropomyosin in the muscles of the rabbit roughly correlate with the speed of contraction¹³ there was no change in this ratio during similar periods of cross innervation. Troponin C was not examined after cross innervation for there is evidence that this protein is very similar, if not identical, in fast and slow skeletal muscle^{17,18}. Neither was troponin T studied although different forms of this protein exist in the red and white skeletal muscle of the chicken^{19,20}. We conclude that the type of innervation markedly affects the polymorphic form of troponin I in the muscle, but not the

tropomyosin and probably not the troponin C. This implies that different factors are involved in regulating the genes concerned in the synthesis of the individual proteins of the regulatory system.
